ABSTRACT

COLLISIONAL MOLECULAR ORIENTATION TRANSFER

FACILITATED POLARIZATION SPECTRA OF THE $A^1\Sigma_u^+$ AND $b^3\Pi_u$ STATES

OF THE $^{85}Rb_2$ AND Cs_2 DIMERS

By   Jianmei Bai
Doctor of Philosophy
Temple University, 2011
Thesis Advisor: Dr. A. Marjatta Lyyra

The focus of this thesis is the study of the strongly perturbed $A^1\Sigma_u^+ \sim b^3\Pi_u$ complex of electronic states of the Rb_2 and Cs_2 dimers. Using collisional molecular orientation transfer facilitated high resolution V- type optical-optical double-resonance (OODR) polarization spectroscopy, it was possible to observe a much larger number of rovibrational levels in the $A^1\Sigma_u^+ \sim b^3\Pi_u$ complex of states than anticipated.

In addition to the direct *P, R* doublets, we have observed probe laser signals from a large number of collisionally populated rotational levels. Angular momentum changes up to ΔJ = 58 were observed in the recorded $^{85}Rb_2$ spectra. Observation of these satellite lines is based on transfer of both population and orientation from the rovibrational levels involved in the pump laser excitation to neighboring levels in a collision of the molecule with atomic perturbers.

The Discrete variable representation (DVR) method was used to analyze this data combined with other available data in a global deperturbation analysis of the spin-orbit interaction of the strongly perturbed $A^1\Sigma_u^+ \sim b^3\Pi_u$ complex of Rb_2 and Cs_2 electronic states. The resulting experimentally derived potential energy curves and internuclear distance dependent spin-orbit functions are presented in H. Salami et al., Phys. Rev. A**80**, 022515 (2009) and Jianmei Bai et al., Phys. Rev. A**83**, 032514 (2011). In addition, the analysis yields the term values of the rovibrational energy levels and their percentage of singlet and triplet character.

CHAPTER 1

INTRODUCTION

The lowest electronically excited states of alkali dimers, namely the $A^1\Sigma_u^+$ and $b^3\Pi_u$ electronic states (see Figure 1), have been of interest for a long time because they can be used as 'window' states for the excitation of higher singlet or triplet states.

In this Thesis we use collisional orientation transfer facilitated V-type double-resonance polarization spectroscopy to record rovibrational energy level data for the strongly perturbed $A^1\Sigma_u^+ \sim b^3\Pi_u$ complex of electronic states of Rb_2 [1] and Cs_2 [2]. Observation of collisional orientation transfer in polarization spectroscopy was first reported by Schawlow et al. [3] with a buffer gas pressure of several hundred Torr. This led to a loss of spectral resolution, and much lower pressure is needed for the more dense spectra of the heavier alkali dimers. More recently, N. Okada and coworkers [4] observed collisional orientation transfer facilitated polarization spectra of $^{39}K^{85}Rb$ with much lower buffer gas pressure (0.5 Torr) and high resolution.

In this Thesis we utilize this technique for heavier molecules such as Cs_2 for which spectral congestion makes it difficult to find isolated pump transitions. One of the advantages of this approach is the enhanced yield of observed rotational energy levels through the many collisional satellite lines observed per single pump transition compared to the customary strong $\Delta J = \pm 1$ transitions. Another attractive aspect of this technique is

1

Figure 1.1 Theoretical potential curves of Cs_2 calculated by Prof. S. Magnier [5].

its high sensitivity.   As a result we have been able to record spectra for Cs_2 in the probe laser scan range that was previously inaccessible due to very weak Franck-Condon factors from the thermal population of the $X^1\Sigma_g^+$ ground state.

 This Thesis consists of 6 chapters. Chapter 2 gives an introduction to diatomic molecules.   It starts with the Born-Oppenheimer approximation followed by the Schrodinger equation for the diatomic molecular system. The Rydberg-Klein-Rees (RKR) method for constructing molecular potential curves and Hund's coupling cases are introduced in this chapter. This chapter also includes a brief introduction to electric dipole selection rules for transitions between electronic states and the spin-orbit operator for molecular transitions. The spin-orbit coupling operator will be also described.

 In Chapter 3 we describe different types of polarization spectroscopy. These include polarization spectroscopy with 1) a single tunable laser and 2) two independently tunable lasers including collisional transfer of molecular orientation.   The advantages of the polarization technique are presented at the end of the chapter. In Chapter 4 we describe the setup with a brief description of the equipment used in the experiment.

 In Chapter 5 we present the spectra of the Rb_2 and Cs_2 polarization experiments. Spectral lines due to collision-induced energy transfer with ΔJ up to 58 were observed in the Rb_2 spectra. With a very weak probe laser Franck-Condon factors, collisional satellite lines with ΔJ up to 12 were observed per vibrational level in the Cs_2 spectra.

Finally, Chapter 6 introduces the theoretical discrete variable representation (DVR) method for the analysis of the experimental data.

CHAPTER 2

INTRODUCTION TO DIATOMIC MOLECULAR SPECTROSCOPY

2.1 Introduction to Diatomic Molecule

The experiments described in this thesis involve diatomic molecules, their energy levels, and perturbations such as the spin-orbit interaction.

Let's have a brief look at the properties of diatomic molecules. Each diatomic molecule consists of two atoms with internal degrees of motion such as rotation and vibration, which complicate the spectroscopy of molecules compared to that of atoms. The origins of molecular spectroscopy go back more than a century to the 1880s. It continues to play an important role in science and currently is at the heart of ultracold molecule formation research. In this context accurate spectroscopic determination of the energies of the rovibrational levels and their quantum state character is critical fundamental information.

2.2 Energy Level Structure of Diatomic Molecules

2.2.1 The Born – Oppenheimer Approximation

A molecule is a system that contains many electrons and nuclei. For example, Rb_2 molecule is composed of two Rubidium atoms, and each of them has 37 electrons. There are two Rubidium dimer isotopomers, $^{85}Rb_2$ and $^{87}Rb_2$. Quantum mechanically, it is

impossible to find an exact solution to a multi-body system like this. The mass of the nuclei is much higher than that of an electron, and therefore an electron moves much faster than a nucleus. As a result, the electrons follow the movement of the nuclei and quickly build up a new equilibrium. The Born – Oppenheimer approximation [1], proposed in 1927, assumes that the motion of the electrons and the motion of nuclei can be treated separately. This assumption significantly simplifies the problem of solving the Schrodinger equation for the molecular system.

2.2.2 The Schrodinger Equation of a Diatomic Molecular System

To describe the diatomic molecular system, let's start from the Schrodinger equation for a diatomic molecule:

$$\hat{H}\Psi_i = E_i\Psi_i \tag{2.1}$$

where $\hat{H}$ is the diatomic molecular Hamiltonian, Ψ_i is the eigenfunction of the molecular state i and E_i is the eigenvalue of the corresponding state. The Hamiltonian for a diatomic molecule can be written as:

$$
\begin{aligned}
H &= H^N + H^e + V \\
&= H^N + H^e + V^{NN} + V^{Ne} + V^{ee}
\end{aligned}
\tag{2.2}
$$

where H^N and H^e are the nuclear and electronic energy, respectively. Here V stands for the potential energy, and V^{NN}, V^{Ne}, and V^{ee} are the nuclear – nuclear repulsive energy,

the attractive Coulomb interaction energy between the electrons and the nuclei, and the electron – electron repulsive Coulomb interaction energy, respectively. The Hamiltonian for the diatomic molecule can be further written as:

$$H = \sum_{a=1,2} \frac{P_a^2}{2M_a} + \sum_i \frac{P_i^2}{2m} + \frac{Z_1 Z_2 e^2}{4\pi\varepsilon_0 R} - \sum_a \sum_i \frac{Z_a e^2}{4\pi\varepsilon_0 r_{ia}} + \sum_i \sum_{j>i} \frac{e^2}{4\pi\varepsilon_0 r_{ij}} \tag{2.3}$$

The Greek subscripts refer to the nuclei, and the Roman subscripts refer to the electrons. R is the internuclear distance.

Schrodinger equation determines the energy level structure of the diatomic molecules, but it is not easy to solve approximately. References [2-5] present useful approaches for solving it.

To simplify the Schrodinger equation, two coordinate transformations are applied. The first transformation is from a space system which has an arbitrary origin (xyz) to a space coordinate system (XYZ) with the origin at the center mass of the nuclei. In the second transformation the space coordinate system (XYZ) is then transformed into a molecular coordinate system. Both systems share the same origin.

The second transformation can be described by the three Euler angles R, θ and ϕ. In terms of Euler angles, we can express the Hamiltonian in the form:

$$H = H^N(R,\theta,\phi) + H^e(r) + V(r,R) \qquad (2.4)$$

As stated earlier, the velocities of the electrons are much bigger than those for the nuclei. In the Born-Oppenheimer approximation, the motions of the electrons and the nuclei can be treated separately. The wavefunction can be written as

$$\Psi_i^{BO} = \varphi_{ie}(r,R)\chi_{v,J}(R,\theta,\phi) \qquad (2.5)$$

where $\varphi_{ie}(r,R)$ stands for the electronic wavefunction and $\chi_{v,J}(R,\theta,\phi)$ stands for the vibrational- rotational wavefunction of the nuclei. Here v is the vibrational quantum number and J is rotational quantum number.

The energy of the molecule can be written approximately as the sum of the electronic energy T $_{i,e}$, the vibrational energy G(v) and the rotational energy F(J):

$$E_i = T_{i,e} + G(v) + F(J) \qquad (2.6)$$

The time independent Schrodinger equation can be separated into electronic and nuclear wave equations:

$$[H^e(r,R) + V(r,R)]\varphi_{i,e}(r,R) = E_{i,e}(R)\varphi_{i,e}(r,R) \qquad (2.7)$$

$$[H^N(R,\theta,\phi) + E_{i,e}(R)]\chi_{v,J}(R,\theta,\phi) = E_N\chi_{v,J}(R,\theta,\phi) \qquad (2.8)$$

The potential energy curve $E_{i,e}(R)$ can be obtained by solving the electronic eigenvalue equation for different internuclear distance values R.

2.2.3 Electronic States of Diatomic Molecular

According to the Born- Oppenheimer approximation, the motion of the electrons and the motion of nuclei can be treated separately. As a result, the molecular energy levels can be classified in terms of electronic and nuclear states. The nuclear states include vibrational states and rotational states.

Figure 2.1 illustrates the angular momenta for a diatomic molecule and their projections on the internuclear axis. $\boldsymbol{L}$ is the electronic orbital angular momentum. Neglecting the electron spin, $\boldsymbol{L}$ is not a constant, although the component about the inter-nuclear axis $\boldsymbol{L_z}$ is conserved. In a diatomic molecule the potential in which the electrons move is symmetric about the internuclear axis.

Let $\varLambda$ represent the absolute value of the projection of the electronic orbital momentum (L) along the internuclear axis. For a given value of the orbital electronic quantum number (L), $\varLambda$ can take the values

$$\varLambda = 0, 1, 2, \ \ldots, L . \tag{2.9}$$
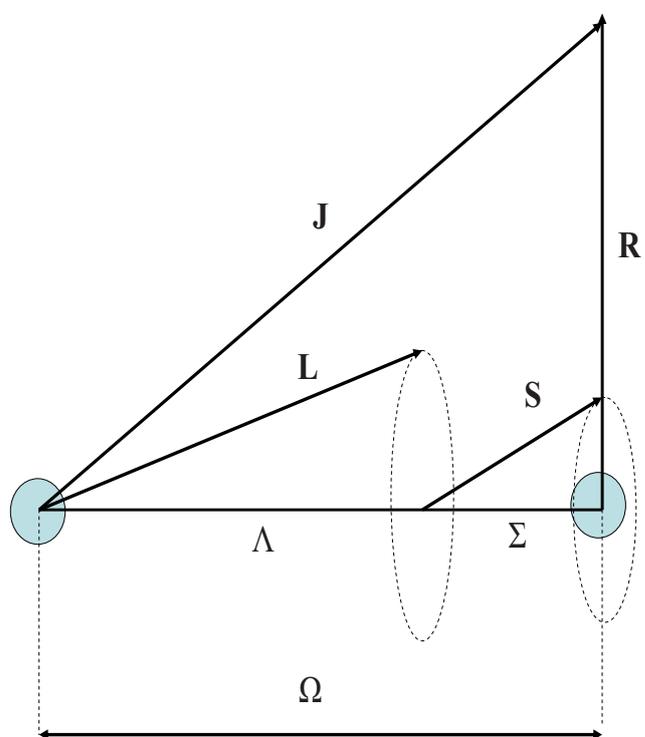

Figure 2.1 Angular momentum and good quantum numbers in a diatomic molecule.

When $\varLambda = 0, 1, 2, 3, \ldots$, the electronic state is accordingly labeled $\Sigma, \Pi, \Delta, \Phi, \ldots$ state. $\Pi, \Delta, \Phi, \ldots$ states are doubly degenerate, while the Σ states are non – degenerate.

Now let's consider the electron spin for diatomic molecules. The spins of the individual electrons form a resultant spin S. The electron spin component along the internuclear axis M_S is conserved, and it is denoted by Σ. Σ can have $2S + 1$ different possible values:

$$\Sigma = S,\ S\text{-}1,\ S\text{-}2,\ \ldots,\ \text{-}S \tag{2.10}$$

In general these $2S+1$ states are non-degenerate.

When we add the electronic angular momentum L and the component of S along the internuclear axis together, the resultant is the total electronic angular momentum about the internuclear axis, which is denoted by $\mathbf{\Omega}$:

$$\mathbf{\Omega} = \Lambda + \Sigma \tag{2.11}$$

If $\Lambda \neq 0$, for a given value of Λ bigger than S, $\Lambda + \Sigma$ can have $2S +1$ different values with different energies. This is called spin-orbit splitting. However, if $\Lambda =0$, there is no magnetic field in the direction of the internuclear axis and no energy splitting. The vector $\mathbf{R}$ in Figure 2.1 represents the quantized rotational angular momentum of the nuclei.

2.2.4 Vibrational States and Rotational States of a Diatomic Molecule

The vibrational and rotational spectra of diatomic molecules are an important area of spectroscopy with many practical applications and is discussed in [2,6] and many other books.

A diatomic molecule is composed of two atoms and can be considered a vibrating rotator. To understand the rovibrational states of the diatomic molecule, let's start from the so-called dumbbell model, which is shown in Figure 2.2. In this model, we assume that the distance between the two atoms is fixed, which means the molecule is considered to be a rigid rotor. This leads to the equation for the rotational energy:

$$E = \frac{1}{2} I \omega^2 \tag{2.12}$$

where ω is the angular velocity of the rotation, and I is the moment of interia of the system about the axis of rotation given by:

$$I = \mu r^2 \tag{2.13}$$

Here m_1 and m_2 are the masses of the first atom and the second atom, respectively, $\mu = \dfrac{m_1 m_2}{m_1 + m_2}$ is the reduced mass of the molecule and r is the distance between the atoms.
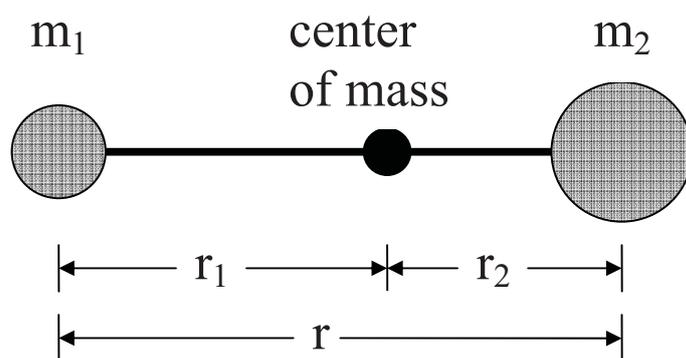

Figure 2.2 Dumbbell model of a diatomic molecule.

We now consider that the diatomic molecule is also vibrating while it is rotating. The Schrodinger equation for this vibrating rotor can be written as:

$$\left[\frac{-\hbar^2}{2\mu}\nabla^2 + V(R)\right]\Psi = E\Psi .$$

(2.15)

According to Ref [7,8] , the potential energy curve V(R) can be expanded in the form of a polynomial around the equilibrium point $R=R_e$

$$V(R) = a_0(\frac{R-R_e}{R_e})^2[1 + a_1(\frac{R-R_e}{R_e}) + a_2(\frac{R-R_e}{R_e})^2 + \cdots]$$

(2.16)

By using the first – order semiclassical quantization condition from Wentzel – Kramers – Brillouin (WKB) theory, Dunham obtained an analytical expression for the energy levels of the vibrating rotor. Experimentally, the Dunham coefficients [8] can be obtained by fitting the term values of the rovibrational levels to the Dunham formula, which can be expressed in the form of a double power series

$$E_{v,J} = \sum_{jk} Y_{jk}(v+1/2)^j\left[J(J+1) - \Lambda^2\right]^k$$

(2.17)

where v and J are the vibrational and rotational quantum numbers, respectively, and Λ is the projection of the electronic angular momentum **L** on the internuclear axis.

According to Dunham's formula, there is also a non-vanishing term Y_{00}, which modifies the energy of the vibrational level $v = 0$. It can be written in terms of the other Dunham's constants as:

$$Y_{00} = \frac{Y_{01}}{4} - \frac{Y_{11}Y_{10}}{12Y_{01}} + \frac{Y_{11}^2 Y_{10}^2}{144Y_{01}^3} + \frac{Y_{20}}{4} \qquad (2.18)$$

The customary energy level expressions are:

$$G(v) = \omega_e(v + 1/2) - \omega_e x_e(v + 1/2)^2 + \omega_e y_e(v + 1/2)^3 \qquad (2.19)$$

for the vibrational term values, and

$$F_v(J) = B_v J(J + 1) - D_v[J(J + 1)]^2 + \dots \qquad (2.20)$$

for the rotational terms in a given vibrational level. Here ω_e is the harmonic vibrational frequency, $\omega_e x_e$ is the vibrational anharmonicity constant, B_v is the rotational constant for a given vibrational level, and D_v is the centrifugal distortion constant. D_v is often very small compared to B_v, and as a result the second term can be neglected.

When we compare these two equations with the Dunham expansion, it is clear that Y_{10} is the harmonic oscillator frequency ω_e, Y_{00} is the electronic energy term, also denoted by T_e, and Y_{01} is the rotational constant B_e of a rigid rotator.

If we use Rb_2 as an example, the magnitudes for the electronic energy, vibrational energy and rotational energy are of the order of 10^4, 10^2 and 1 cm^{-1}, respectively. The electronic transitions of the alkali molecules fall into the visible and near – infrared spectral regions, which are within the range of the wavelengths of our tunable frequency stabilized narrow band laser systems.

2.2.5 The RKR Method

The Dunham formula works well in the lower part of the potential well where it is approximately parabolic. It is not accurate at large internuclear distance where the potential curve approaches the dissociation limit. The Rydberg-Klein-Rees (RKR) method [9-12] is widely used to determine diatomic molecular potential energy curves. The RKR method is based on two Klein integrals

$$R_+(v) - R_-(v) = 2 \left(\frac{C}{u}\right)^{1/2} \int_{v_{min}}^{v} \frac{dv'}{\sqrt{G_v - G_{v'}}} = 2f \qquad (2.21)$$

$$\frac{1}{R_-(v)} - \frac{1}{R_+(v)} = 2 \left(\frac{C}{u}\right)^{1/2} \int_{v_{min}}^{v} \frac{B_{v'}dv'}{\sqrt{G_v - G_{v'}}} = 2g \qquad (2.22)$$

where $R_+(v)$ and $R_-(v)$ are the outer and inner turning points of the potential for vibrational level v with energy term value G (v). B(v) is the inertial rotational constant

for a given vibrational level v, and v_{min} is the minimum vibrational number. Here C is a constant, and μ is the reduced mass.

Calculating the f and g intergrals based on experimental G(v) and B(v) functions, we can write for the inner and outer turning points of molecular vibration:

$$R_- = \left[f^2 + \frac{f}{g} \right]^{\frac{1}{2}} - f \qquad (2.23)$$

$$R_+ = \left[f^2 + \frac{f}{g} \right]^{\frac{1}{2}} + f \qquad (2.24)$$

This can also be expressed as

$$f \equiv \frac{1}{2}(R_+ - R_-) \qquad \text{and} \qquad g \equiv \frac{1}{2}(\frac{1}{R_-} - \frac{1}{R_+}) \qquad (2.25)$$

With the RKR potential obtained from the experimental term values in this manner, the rovibrational eigenvalues and wavefunctions calculated numerically from the radial the Schrodinger equation for the diatomic molecule are more accurate than with the Morse potential.

2.3 Hund's Coupling Cases

In analyzing the coupling of the angular momenta of a diatomic molecule, Hund considered several cases, which cover the vast majority of molecules. Understanding these cases is very important for the analysis of experimental spectra.

Hund's case (a):   Fig 2.3 (a) is the vector diagram for Hund's case (a). L is the electronic orbital angular momentum, and Λ represents the component of the electronic orbital momentum (L) along the internuclear axis. In terms of the quantum value of the electronic orbital quantum number L, the quantum number Λ can take the values:

$$\Lambda = 0,\ 1,\ 2,\ \ldots ,\ L . \tag{2.26}$$

When $\Lambda = 0,\ 1,\ 2,\ 3,\ \ldots$, the molecular electronic state is denoted by $\Sigma,\ \Pi,\ \Delta,\ \Phi,\ \ldots$ state. The sum of the individual electron spin angular momenta is designated by S. Hund's case (a) assumes that the electronic motion is coupled very strongly to the line joining the nuclei while the interaction of the nuclear rotation with the electronic motion (spin as well as orbital) is very weak. The electronic angular momentum and spin are coupled individually to the internuclear axis.   The total electronic angular momentum about the internuclear axis Ω and the angular momentum R of nuclear rotation form the total angular momentum J, which is a constant in magnitude and direction. While Ω and R rotate about J, the L and S process about the internuclear axis has a much higher frequency.
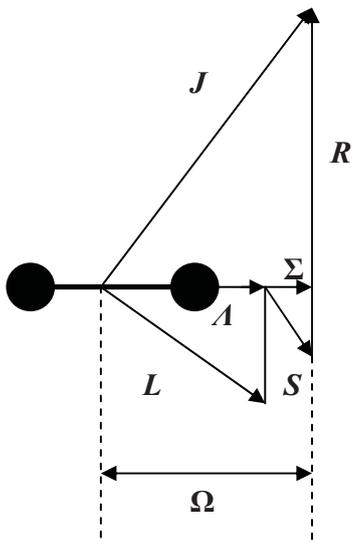

Hund's case (a)
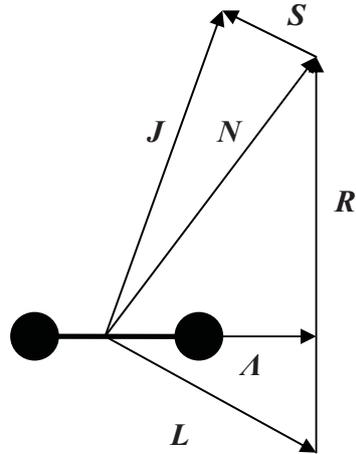

Hund's case (b)
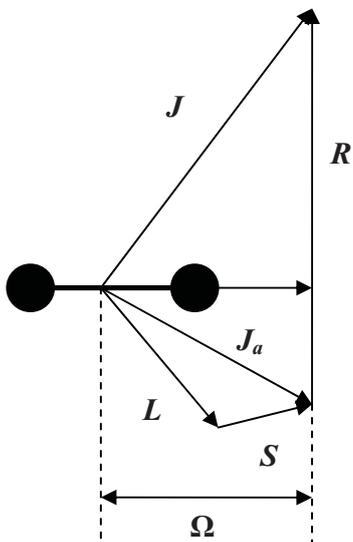

Hund's case (c)
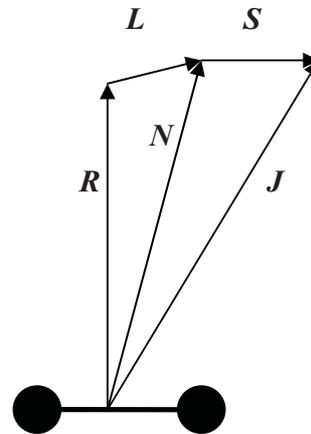

Hund's case (d)

Figure 2.3 Hund's coupling cases.

Hund's case (b): When $\Lambda = 0$ and $S \neq 0$, the spin vector $\boldsymbol{S}$ is not coupled to the internuclear axis at all, and we call this case Hund's case (b). The electronic angular momentum about the internuclear axis $\boldsymbol{\Omega}$ is not defined in Hund's case (b). Even if $\Lambda \neq 0$, unlike what happens in Hund's case (a), for some of the light molecules $\boldsymbol{S}$ may be only very weakly coupled to the internuclear axis. Hund's case (b) applies when the coupling of $\boldsymbol{S}$ to the internuclear axis is zero or weak.

Hund's case (c): In Hund's case (c), the interaction between $\boldsymbol{L}$ and $\boldsymbol{S}$ is stronger than the interaction with the internuclear axis. $\boldsymbol{L}$ and $\boldsymbol{S}$ are coupled together to form a resultant $\boldsymbol{J_a}$, which has component $\boldsymbol{\Omega}$ along the internuclear axis. As in Hund's case (a), $\boldsymbol{\Omega}$ and $\boldsymbol{R}$ form the resultant momentum $\boldsymbol{J}$.

Hund's case (d): Hund's case (d) applies if the coupling between $\boldsymbol{L}$ and the internuclear axis is very weak while that between $\boldsymbol{L}$ and the rotation axis is strong. The angular momentum of nuclear $\boldsymbol{R}$ and $\boldsymbol{L}$ are coupled to form $\boldsymbol{N}$, which is the total angular momentum apart from spin. $\boldsymbol{N}$ and $\boldsymbol{S}$ form the total angular momentum $\boldsymbol{J}$.

2.4 Selections Rules of Transitions between Different Molecular States

External electric or magnetic fields contribute additional terms to the molecular Hamiltonian. As a result of that, two different molecular states can be coupled, and this leads to transitions from one state to another. The transition probabilities and intensities

can be obtained from rovibrational wavefunctions and electronic transition dipole moment functions between different electronic states.

2.4.1 Selection Rules of Rotational Transitions

Let's first look at the selection rules for the rotational quantum number J. Using M_x, M_y and M_z to denote the electric transition dipole moment in the x,y,z directions respectively and $R_x^{J'M'J''M''}$, $R_y^{J'M'J''M''}$ and $R_z^{J'M'J''M''}$ to denote the corresponding matrix elements of the electric transition dipole moment, we consider the matrix elements:

$$R_x^{J'M'J''M''} = \int \psi_r^{J'M'*} M_x \psi_r^{J''M''} d\tau$$

$$R_y^{J'M'J''M''} = \int \psi_r^{J'M'*} M_y \psi_r^{J''M''} d\tau$$

$$R_z^{J'M'J''M''} = \int \psi_r^{J'M'*} M_z \psi_r^{J''M''} d\tau \qquad (2.27)$$

Here $\psi_r^{J'M'}$ and $\psi_r^{J''M''}$ are the eigenfunctions of the higher state and the lower state, respectively. We only consider electric dipole transitions because they are much more probable than electric quadrupole or magnetic dipole transition.

If the matrix element $R^{J'M'J''M''}$ differs from zero, the transition is possible but not when $R^{J'M'J''M''}$ is zero. This leads to selection rules for the rotational transition:

$$\Delta J = J'-J''= \pm 1 \qquad \text{for } \Omega = 0$$

$$\Delta J = J'-J''= 0, \pm 1 \qquad \text{for } \Omega \neq 0 \qquad (2.28)$$

In a common spectroscopic notation, the molecular transitions with different ΔJ values are defined by:

$$P(J") \quad \text{when} \quad \Delta J = -1$$

$$Q(J") \quad \text{when} \quad \Delta J = 0$$

$$R(J") \quad \text{when} \quad \Delta J = 1 \tag{2.29}$$

2.4.2 Selection Rules of the Vibrational Transitions; the Franck – Condon Principle

The vibrational transitions between different electronic states are governed by the Franck – Condon principle which states: *The electron jump in a molecule takes place so rapidly in comparison to the vibrational motion that immediately afterwards the nuclei still have very nearly the same relative position and velocity as before the jump.* This kind of transition is called a vertical transition.

The intensity of a vibrational transition is proportional to the square of the overlap integral between the vibrational wavefunctions of the two states involved. We call the degree of overlap of the wavefunctions for the initial vibrational state and the final vibrational state the Franck – Condon factors (FCF). The FCF of a rovibronic transition can be expressed as:

$$FCF = \left| \int \psi_{v'}^{J'M'} \psi_{v"}^{J"M"} d\tau \right|^2 \tag{2.30}$$

here $\psi_{v''}^{J''M''}$ and $\psi_{v'}^{J'M'}$ are the wave functions of the two electronic states coupled by the electric dipole transition. In our experiment, we calculated FCFs for the transitions of different vibrational levels by using the LEVEL program developed by LeRoy [13]. The LEVEL program takes the potential curves of the electronic states involved in the transition from the input file and solves the radial Schrodinger equation numerically. It then calculates the FCFs as output. If transition dipole moments are, either experimentally or theoretically, the FCF information can be augmented by calculating the corresponding transition dipole matrix elements.

In choosing the optimal pump laser transition for an experiment, the initial choice is made based on the FCF calculations and available laser wavelength. Knowing the FCFs is also important for predicting and interpreting the signal to noise ratios in the experiments. This is illustrated in this Thesis when we compare the strengths of the Cs_2 and Rb_2 polarization spectroscopy signals. More details about the calculations of the FCFs can be found in Ref. [14].

2.4.3 Electric Dipole Selection Rules of Electronic Transitions

Let's introduce the parity operator **E*** which inverts all of the coordinates of the diatomic molecule in the laboratory frame:

$$\mathbf{E^*}\psi\ (X,\ Y,\ Z) = \psi\ (-X,\ -Y,\ -Z)$$

$$= \pm\ \psi\ (X,\ Y,\ Z) \tag{2.30}$$

Here ψ (X, Y, Z) is the total rovibronic wavefunction of the diatomic molecule. If an electronic state does not change sign under reflection, the electronic state has positive (+) total parity, and if it does change sign under reflection, the state has negative (-) total parity.

For electronic states with $\Lambda \geq 1$, a level that has positive (+) parity is labeled e if (-1)^J = 1 and f if (-1)^J = -1. For a level with negative (-) parity, the level has e parity if $(-)(-1)^J$ = -1 and f parity if $(-1)(-1)^J$ = 1. The operator $\hat{\imath}$ is a symmetry operation in which the electrons are inverted through the center of the molecule, meaning that:

$$\hat{\imath}\,\psi_{el}(x_i,\, y_i,\, z_i) = \psi_{el}(-x_i,\, -y_i,\, -z_i) = \pm\psi_{el}(x_i,\, y_i,\, z_i) \qquad (2.31)$$

The + sign corresponds to g (gerade) parity and – sign corresponds to u (ungerade) parity.

The following selection rules hold for electronic transitions of diatomic molecules:

- $g \leftrightarrow u$ Transitions from g to g state and from u to u state are forbidden. In our experiment, ungerade intermediate 'window' levels are needed if the purpose is to excite from the ground state (g parity) to higher states which have g parity.

- $e \leftrightarrow f$ when $\Delta J = 0$ and $e \leftrightarrow e,\ f \leftrightarrow f$ when $\Delta J = \pm 1$

- $s \leftrightarrow s,\ a \leftrightarrow a$ This means that symmetric rotational levels can only be coupled with symmetric levels and antisymmetric levels can only be coupled with antisymmetric levels.

- $\Delta\Lambda = 0, \pm 1$, which means that $\Sigma - \Sigma, \Sigma - \Pi, \Pi - \Delta, \ldots$ transitions are allowed while $\Sigma - \Delta$ transitions are forbidden. Only Σ^{+} - Σ^{+} and Σ^{-} - Σ^{-} are allowed.

- $\Delta S = 0$, which means that transitions are allowed only between states with the same spin multiplicity.   Singlet $\leftrightarrow$ triplet transitions are forbidden.

2.5 Terms Neglected in the Born - Oppenheimer Approximation

2.5.1 The Spin – Orbit Operator

The interaction between the electron spin and the electron orbital momenta is called the spin – orbit interaction. The spin – orbit Hamiltonian H^{so} for a diatomic molecule can be expressed as:

$$H^{so} = \frac{gsu_B}{c} \sum_i \left[\frac{Z_A e}{r_{iA}^3}[(r_i - r_A) \times \frac{\mathbf{v}_i}{2}] \cdot s_i + \frac{Z_B e}{r_{iB}^3}[(r_i - r_B) \times \frac{\mathbf{v}_i}{2}] \cdot s_i \right]$$

$$- \frac{gsu_B}{c} \sum_{i \neq j} \frac{e}{r_{ij}^3}[(r_i - r_j) \times (\frac{1}{2}\mathbf{v}_i - \mathbf{v}_j)] \cdot \mathbf{s}_i \qquad (2.32)$$

where gs is the Lande electronic factor, u_B is the Bohr magneton which is $\dfrac{e\hbar}{2mc}$ and $\mathbf{v}_i$ is the velocity of the ith electron measured in the molecule fixed coordinate frame.

To simplify the equation, we can replace $\mathbf{v}_i$ by p_i/m. Here p_i is the momentum of the electron measured in the molecule fixed coordinate frame. The angular momentum operator l_i can be expressed in the form

$$l_{iA} = (1/\hbar)(r_{iA} \times p_i), \qquad l_{iB} = (1/\hbar)(r_{iB} \times p_i)$$

The expression for the spin – orbit Hamiltonian becomes [5] :

$$H^{so} = \frac{a^2}{2} \sum_i \left[\frac{Z_A}{r_{iA}^3} l_{iA} \bullet s_i + \frac{Z_B}{r_{iB}^3} l_{iB} \bullet s_i \right] - \frac{a^2}{2} \sum_{i,j,i\neq j} \frac{1}{r_{ij}^3}(r_{ij} \times p_i)(s_i + 2s_j) \qquad (2.33)$$

Here a is the fine structure constant, $a = \dfrac{e^2}{\hbar c} = \dfrac{1}{137.036}$.

This equation includes two parts. The first part is a single – electron operator and it represents the interaction between each of the electrons and the two nuclei Z_A and Z_B. The second part of the equation describes the spin-other-orbit interactions between electrons which can be included in the first term as a screening effect. The spin-orbit Hamiltonian can then be written as:

$$H = \sum_i a_i l_i \cdot s_i \quad \text{with} \quad a_i l_i = \sum_K \frac{a^2}{2} \frac{Z_{eff,K}}{r_{iK}^3} l_{iK} \qquad (2.34)$$

where $Z_{eff,K}$, the effective charge of the K'th nucleus, is less than Z_K and l_{iK} is the orbital angular momentum of the ith electron and the K'th nucleus.

2.5.2 Perturbation Selection Rules

Selection rules for perturbation [2,15] are determined by the quantum numbers and symmetry properties of the two states considered:

(1) $\Delta J = 0$, which means both of the states should have the same total angular momentum.

(2) The spin of the two states can be differ by 0 or ± 1, which can be expressed as $\Delta S = 0, \pm 1$.

(3) In Hund's coupling case (a) and (b) where Λ is defined, $\Delta \Lambda = 0, \pm 1$. In Hund's coupling case (c), where Ω is defined instead of Λ, the rule becomes $\Delta \Omega = 0, \pm 1$.

(4) The two energy levels must be both positive or both negative, which means $+ \leftrightarrow +$, $- \leftrightarrow -$, but not $+ \leftrightarrow -$.

(5) Both energy levels must have the same symmetry in the nuclei, which means s $\leftrightarrow$ s, a $\leftrightarrow$ a , but s $\leftarrow\!/\!\rightarrow$ a.

The $A^1\Sigma_u^+$ and $b^3\Pi_u$ states of alkali dimers are coupled by the spin – orbit interaction, and they have both singlet and triplet character. Due to the electric dipole selection rule $\Delta S = 0$, the higher lying triplet states of alkali dimers would not be accessible if there were no spin – orbit interaction.

CHAPTER 3

THEORETICAL BACKGROUND OF POLARIZATION   SPECTROSCOPY

3.1   Introduction to Doppler-free Polarization Spectroscopy

The laser is a powerful tool in molecular spectroscopy. The special characteristics of lasers such as high intensity and extremely small bandwidth have increased the spectral resolution and sensitivity by several orders of magnitude. Lasers have enabled scientists to study the energy level structure of molecules and atoms in much greater detail. In this chapter, we will highlight the use of lasers in polarization spectroscopy.

One of the advantages of single longitudinal mode lasers is that they can be used to overcome limitations caused by the Doppler broadening, since the narrow bandwidth of the tunable laser interacts with a chosen velocity group within the Doppler profile. Doppler broadening is caused by the thermal motion of the absorbing and emitting molecules, and it contributes to the spectral linewidth of gas phase molecules.   Doppler broadening reduces the spectral resolution and makes it difficult to assign spectral lines. Reducing the Doppler- broadening increases the resolution so that isotope shifts, hyperfine splitting and Zeeman splitting can be studied.

The techniques of two-photon absorption spectroscopy, saturation spectroscopy, and polarization spectroscopy use single mode lasers and effectively reduce the Doppler broadening [1].

3.1.1 Two-Photon Absorption Spectroscopy

Two-photon absorption spectroscopy was first proposed by Vasilenko *et al*. in1970 [2]. A laser beam is divided into two counter-propagating beams. Assume that the gas phase molecule moves at velocity **v** in the laboratory frame. In the frame of this molecule, the frequencies of the two laser beams are shifted to $\omega_1 = \omega_0 - \mathbf{k} \cdot \mathbf{v}$ and $\omega_2 = \omega_0 + \mathbf{k} \cdot \mathbf{v}$, respectively. Here ω_0 is the frequency of the laser beams in the laboratory frame. When the molecule absorbs photons ω_1 and ω_2, the two photon transition is independent of Doppler broadening, because $\omega_1 + \omega_2 = (\omega_0 - \mathbf{k} \cdot \mathbf{v}) + (\omega_0 + \mathbf{k} \cdot \mathbf{v}) = 2\omega_0$.

3.1.2 Saturation Spectroscopy

Saturation spectroscopy is also called Lamb-dip spectroscopy. In this technique, a strong pump laser beam and a weak probe laser beam are arranged in a counter propagating geometry, and both of them pass through the gas phase sample. When the pump laser beam is strong enough and it is tuned to a transition of the gas phase sample, the transition will be saturated. The weak probe laser can not add more excitation of the **k·v**=0 molecules, which makes the signal smaller than the other velocity groups [1]. Thus, a narrow Lamb dip can be observed at the center of the Doppler profile.

3.1.3 Polarization Spectroscopy

In laser spectroscopy spectra are recorded by either the absorption or emission of light. What makes the polarization spectroscopy technique unique is that there is a signal whenever the polarization direction of the probe laser changes. The change of the polarization of the probe laser beam is induced by a much stronger pump beam, which produces an anisotropic distribution of the magnetic sublevels and thus causes orientation of the molecular angular momentum.

3.2 Polarization Spectroscopy

3.2.1 Polarized Light

Light can be polarized if it interacts with matter with asymmetric optical properties in the transverse plane relative to the propagation direction. In our polarization spectroscopy experiments on the Rb_2 and Cs_2 dimers, the pump beam is circularly polarized, and the probe beam is linearly polarized.

3.2.1.1 How to Produce Linearly Polarized Light

There are four general ways that linearly polarized light can be produced: dichroism, birefringence, reflection and scattering.

Dichroism

When light passes through a dichroic polarizer, the component of the **E**-field which oscillates perpendicular to the direction of the transmission axis will be absorbed by the polarizer. The component that has the same vibration direction as the transmission axis is transmitted, so that the transmitted light is linearly polarized.

Birefringence

When light interacts with a birefringent material, there are two different refracted beams due to the two indices of refraction ($n_\perp$ and $n_\parallel$) of the birefringent material. If the light goes through a crystal which has thickness d, the optical path difference between the two refracted beams is:

$$\Delta = \left| n_\perp - n_\parallel \right| d \tag{3.1}$$

and the corresponding phase difference is:

$$\Delta\varphi = 2\pi\left(\frac{\Delta}{\lambda_0}\right) = \left(\frac{2\pi}{\lambda_0}\right) \left| n_\perp - n_\parallel \right| d \tag{3.2}$$

where λ_0 is the wavelength of the light in vacuum. From equation (3.2) we note that for a certain wavelength λ_0, $\Delta\varphi$ is proportional to the thickness d of the birefringent material. There are retardation plates in which the thickness d of the birefringent material can be adjusted continuously. This kind of device is called a compensator. We used a Babinet-Soleil compensator from Karl Lambrecht Inc., Chicago, in our polarization spectroscopy experiments to convert the linearly polarized pump laser beam into a circularly polarized beam.

Reflection

When light travels from one dielectric material (n_1) to another dielectric material (n_2) is incident at Brewster's angle

$$\theta = \tan^{-1}(\frac{n_2}{n_1}),\qquad\qquad\qquad (3.3)$$

The reflected and refracted rays are perpendicular and the reflected ray is linearly polarized.

Scattering

When unpolarized light interacts with the molecules inside the scattering material, radiation will be re-emitted in all directions. When viewed from a direction perpendicular to the incoming light direction, the scattered light is partially polarized. An example of this is the partial polarization of scattered sunlight, which can be seen by looking at the sky through a polarizing filter while it is rotated. Because polarization by scattering is weak and far from perfect, we do not use this method to produce polarized light in our experiment.

3.2.1.2 How to Produce Circularly Polarized Light

Linear polarizers and a λ/4 circular polarizer were used in our polarization spectroscopy experiment. The linear polarizer is a Glan Thompson polarizer. The λ/4 circular polarizer is a Babinet-Soleil compensator from Karl Lambrecht, Inc.

Babinet-Soleil Compensator

As explained above, the Babinet Soleil compensator is an optical device made from a birefringent material with continuously adjustable thickness. One of the wedges is attached to the parallel plate while the other one is attached to a micrometer. The micrometer can be adjusted to vary the thickness of the wedges with a least count of 0.01mm. An optional rotatable mount (KLC Model DCGF) is used for easy and accurate adjustment of the compensator azimuth with an accuracy of less than one arc minute. A dovetail slide permits the compensator to be easily removed from the path of the light beam.

In our polarization spectroscopy experiment, we tuned the thickness of the Babinet-Soleil compensator so that $\Delta\varphi = \pi/2$ for the pump beam. Thus we also call our Babinet-Soleil compensator the $\lambda/4$ plate. The circularly polarized pump beam is produced in two stages. First the laser beam passes through a linear polarizer in front of the Babinet - Soleil compensator to eliminate any ellipticity in its polarization. Second, the $\lambda/4$ plate is adjusted to form a 45 degree angle relative to the transmission axis of the linear polarizer, and circularly polarized light can be produced at any wavelength within the tuning range of the laser by adjusting the Babinet-Soleil compensator for the wavelength the laser.
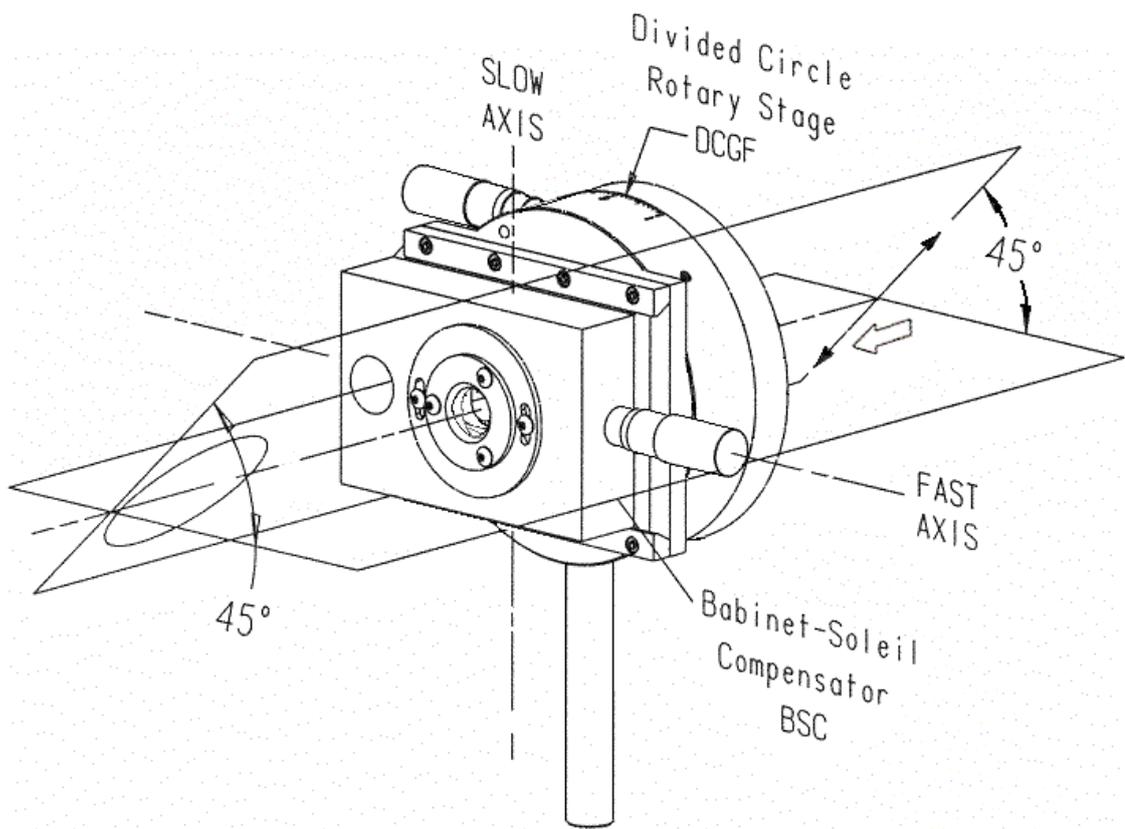

Figure 3.1 The Babinet-Soleil compensator that was used in our polarization experiments to produce circularly polarized laser beam.

To confirm that the pump beam is circularly polarized, we mounted a linear polarizer and a power meter after the λ/4 Babinet Soleil compensator. The power of the circularly polarized beam should be distributed equally in every direction that is perpendicular to its propagation axis. Thus the reading of the power meter should not change much during the rotation of the linear polarizer used as an analyzer.

3.2.2 Basic Principle of Polarization Spectroscopy

The basic principles of the polarization spectroscopy technique are discussed clearly in reference [1].

Laser polarization spectroscopy is based on the selection rule of the magnetic sublevel M which is the projection of the total angular momentum quantum number J onto the direction of the light propagation. M'' denotes the quantum number M of the ground state , and M' denotes the quantum number M of the upper state. If a transition is pumped by circularly polarized light, the change of M follows the selection rule $\Delta M = \pm 1$ (- for clockwise circularly polarized laser beam and + for counter clockwise circularly polarized laser beam)

When the pump laser beam is tuned to the $(J',\ M') \leftarrow (J'',\ M'')$ transition and the power is strong enough, the degenerate M sublevels of the rotational level J'' will be partially or completely depleted due to saturation.   But when the pump beam is circularly polarized, some M sublevels will be unaffected. We can see this in Figure 3.2. The upper part of the
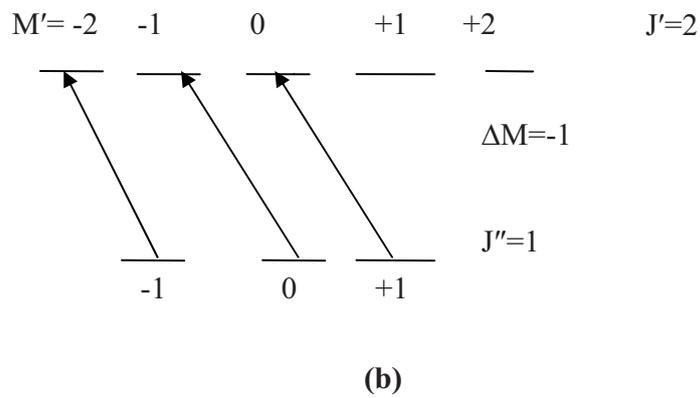

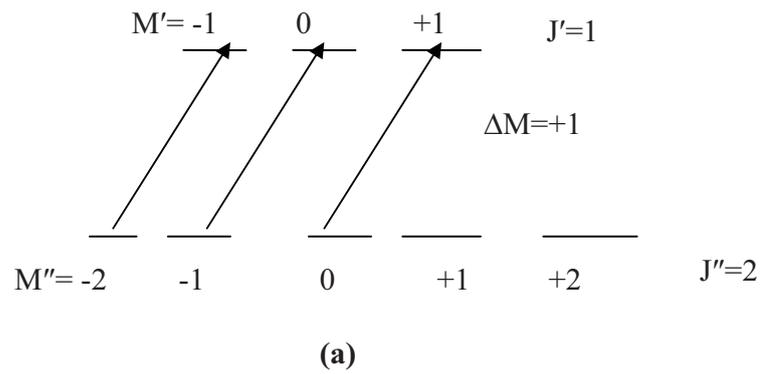

Figure 3.2 Polarization spectroscopy (a) level scheme for a P transition (b) level scheme for an R transition.

figure shows that for $J''=2$, when the transitions are P ($\Delta J = -1$) transitions, the total angular momentum quantum number of the upper level is $J' = 1$. The M sublevels $M''= 1$ and $M'' = 2$ will remain unaffected when $\Delta M = 1$. The lower portion of Figure 3.2 shows that for R ($\Delta J = +1$) transitions, the M sublevels $M' = 1$ and $M' = 2$ are not populated. Thus the population of the M sublevels is anisotropic.

In our polarization spectroscopy experiments, we install a linear polarizer before the heat pipe oven with its transmission axis in the same direction as the polarization direction of the linearly polarized probe laser beam. The counterpropagating linearly polarized probe laser beam can be considered to be made up of equal parts left- and right-circular polarization. When the probe frequency is tuned to a transition sharing either the upper or the lower level in the excitation, the orientation created by the pump causes the two circularly polarized probe components to experience different absorption coefficients (circular dichroism) and different indices of refraction (circular birefringence). Consequently, when the probe beam exits the oven, the two components no longer sum to the initial linear polarization. Instead the beam has a slight elliptical polarization and some fraction of it is transmitted through a final crossed linear polarizer before reaching the detector.

3.2.3 Different Types of Polarization Spectroscopy

There are three basic kinds of polarization spectroscopy:

1. When spectroscopic analysis and the assignment of vibrational and rotational quantum numbers is not expected to be too difficult, a single laser beam can be split into strong pump beam (75%) and weak probe beam (25%) with no labeling [3]. By labeling we mean that the quantum numbers of the terminal levels of a separate pump beam transition are well known and the probe laser excitations originate from one of these levels, leading to automatic assignment of the probe transitions. If a single laser, that is tuned, is split into two components, all transitions within the tuning range of the laser can be excited and will have to be separately assigned. The two beams are in a counterpropagating geometry and overlap at the center of the heat pipe oven in the region of the sample molecule vapor. The pump beam is circularly polarized and two crossed linear polarizers are installed in the path of the probe beam. The laser frequency is continuously scanned. The circularly polarized pump beam will generate an anisotropic magnetic sublevel distribution in the lower and upper rotational levels involved in the pump laser transitions. The linearly polarized probe laser beam becomes slightly elliptically polarized because the left and right circularly polarized components that the linear polarization consists of are absorbed by different amounts. Thus part of the probe beam passes through the second linear polarizer and is detected by the PMT detector. A simple sketch of this experimental set-up is shown in Fig. 3.3. The assignments of the polarization signals are based on relatively good initial molecular constants. In the particular case of reference [3] additional polarization spectroscopic signals were used in the global deperturbation analysis. The advantage of this type of polarization spectroscopy is that all possible rovibrational transitions are observed with high resolution, and the observed transitions are not limited by the labeling of the pump transition provided that we know the

vibrational and rotational constants well enough to identify the transitions. This technique was first applied to study the hyperfine structure in the hydrogen atom Balmer-β transition [4], and it has been widely used in molecular spectroscopy [5-8] .

2. Optical – optical double resonance polarization spectroscopy [9-11] is preferred when the spectral peaks are hard to assign. The difference between this technique and the one we discussed above is that two different laser beams are used. A strong circularly polarized pump laser pumps a certain well known transition from ground state X (v'', J'') to an excited state, while the much weaker probe laser is scanning. From the selection rules, the main lines that can be observed are the probe transitions with $J'=J''\pm1$.

3. Satellite lines with weaker intensities than the main lines can sometimes be observed because the orientation of the anisotropic field can partially survive the collision – induced transfer [12-21]. The collision - induced lines enlarge the range of rotational lines that can be identified in the experiment. More details about this kind of polarization spectroscopy will be given in the later chapters.
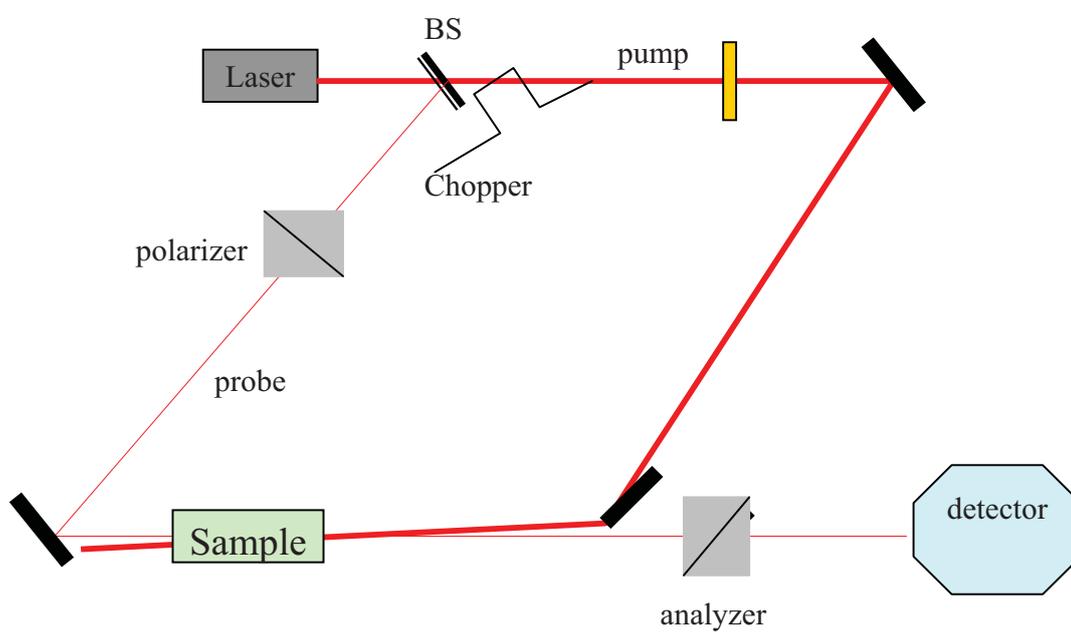

Figure 3.3 The scheme of one laser polarization spectroscopy setup.

3.2.4 Line Profiles of Polarization Signals

The linearly polarized probe wave can be expressed as [1], [22]:

$$E = E_0 e^{i(\omega t - kz)} \quad , \quad E_0 = \{E_{0x}, 0, 0\},$$

Because the linearly polarized beam can be considered to be composed of two circularly polarized components, we can rewrite this electric field as:

$$E^+ = \frac{1}{2} E_0 (x + iy) e^{-i\omega t}$$

$$E^- = \frac{1}{2} E_0 (x - iy) e^{-i\omega t} \tag{3.5}$$

The two components of the linearly polarized beam experience different refractive indices $n_v^{\pm} = \mathrm{Re}[n_v^{\pm}] + i\,\mathrm{Im}[n_v^{\pm}]$ when they propagate through the vapor with length L and $n_\omega^{\pm} = \mathrm{Re}[n_\omega^{\pm}] + i\,\mathrm{Im}[n_\omega^{\pm}]$ when they propagate through the two windows with thickness d. Here the real part of the index of refraction represents the dispersion and the imaginary part represents the absorption. After propagating through the vapor and the two windows, the

electric field of the laser can be expressed as:

$$E^+ = \frac{1}{2} E_0 (x + iy) \exp\left\{ i\left(\frac{2d\omega}{c} \mathrm{Re}[n_\omega^+] + \frac{L\omega}{c} \mathrm{Re}[n_v^+] - \omega t \right) \right\} \exp\left\{ -\left(\frac{2d\omega}{c} \mathrm{Im}[n_\omega^+] + \frac{L\omega}{c} \mathrm{Im}[n_v^+] \right) \right\}$$

$$E^- = \frac{1}{2}E_0(x-iy)\exp\left\{i(\frac{2d\omega}{c}\mathrm{Re}[n_\omega^-]+\frac{L\omega}{c}\mathrm{Re}[n_v^-]-\omega t)\right\}\exp\left\{-(\frac{2d\omega}{c}\mathrm{Im}[n_\omega^-]+\frac{L\omega}{c}\mathrm{Im}[n_v^-])\right\}$$

(3.6)

They can be simplified to

$$E^+ = \frac{1}{2}E_0(x+iy)\exp\{i(b^+ +n^+ -\omega t)\}\exp\{-(\beta^+ +\alpha^+)\}$$

$$E^- = \frac{1}{2}E_0(x-iy)\exp\{i(b^- +n^- -\omega t)\}\exp\{-(\beta^- +\alpha^-)\}$$

(3.7)

if we use

$$b^\pm = \frac{2d\omega}{c}\mathrm{Re}[n_\omega^\pm] \qquad \beta^\pm = \frac{2d\omega}{c}\mathrm{Im}[n_\omega^\pm]$$

$$n^\pm = \frac{L\omega}{c}\mathrm{Re}[n_v^\pm] \qquad \alpha^\pm = \frac{L\omega}{c}\mathrm{Im}[n_v^\pm].$$

Let's define

$$b = \frac{b^+ +b^-}{2}, \qquad \Delta b = \frac{b^+ -b^-}{2}, \qquad b^+ =b+\Delta b, \quad b^- =b-\Delta b;$$

$$\alpha = \frac{\alpha^+ +\alpha^-}{2}, \qquad \Delta\alpha = \frac{\alpha^+ -\alpha^-}{2}, \qquad \alpha^+ =\alpha+\Delta\alpha, \quad \alpha^- =\alpha-\Delta\alpha;$$

$$\beta = \frac{\beta^+ +\beta^-}{2}, \qquad \Delta\beta = \frac{\beta^+ -\beta^-}{2}, \qquad \beta^+ =\beta+\Delta\beta, \quad \beta^- =\beta-\Delta\beta;$$

$$n = \frac{n^+ +n^-}{2}, \qquad \Delta n = \frac{n^+ -n^-}{2}, \qquad n^+ =n+\Delta n, \quad n^- =n-\Delta n$$

and substituting them to (3.7), we can get:

$$E^+ = \frac{1}{2}E_0(x+iy)\exp\{i(b+n-\omega t)\}\exp\{-(\beta+\alpha)\}\exp\{i(\Delta b+\Delta n)\}\exp\{-(\Delta\alpha+\Delta\beta)\}$$

45

$$E^- = \frac{1}{2}E_0(\boldsymbol{x}-i\boldsymbol{y})\exp\{i(b+n-\omega t)\}\exp\{-(\beta+\alpha)\}\exp\{-i(\Delta b+\Delta n)\}\exp\{(\Delta\alpha+\Delta\beta)\}$$

When the beam passes through the second polarizer oriented at an angle θ from the axis perpendicular to the direction of the original polarization, the transmitted electric field can be written as:

$$E_t = \frac{E_0}{2}e^{i(b+n+\omega t)}e^{-(\beta+\alpha)}\{\sin\theta e^{i(\Delta b+\Delta n)}e^{-(\Delta\beta+\Delta\alpha)} + \sin\theta e^{-i(\Delta b+\Delta n)}e^{(\Delta\beta+\Delta\alpha)} +$$
$$i\cos\theta e^{i(\Delta b+\Delta n)}e^{-(\Delta\beta+\Delta\alpha)} - i\cos\theta e^{-i(\Delta b+\Delta n)}e^{(\Delta\beta+\Delta\alpha)}\}$$

$$= \frac{E_0}{2}e^{i(b+n+\omega t)}e^{-(\beta+\alpha)}\{ie^{-i(\Delta b+\Delta n-\theta)}e^{(\Delta\beta+\Delta\alpha)} - ie^{i(\Delta b+\Delta n-\theta)}e^{-(\Delta\beta+\Delta\alpha)}\} \qquad (3.8)$$

The transmitted intensity $I_t(\omega) = c\varepsilon_0 E_t E_t^*$ can be written as:

$$I_t(\omega) = c\varepsilon_0 E_t E_t^*$$

$$= c\varepsilon_0 \frac{E_0^2}{4}e^{-2(\beta+\alpha)}\{e^{2(\Delta\beta+\Delta\alpha)} + e^{-2(\Delta\beta+\Delta\alpha)} - e^{2i(\Delta b+\Delta n-\theta)} - e^{-2i(\Delta b+\Delta n-\theta)}\} \qquad (3.9)$$

$$= c\varepsilon_0 \frac{E_0^2}{4}e^{-2(\beta+\alpha)}\{\cosh(2\Delta\beta+2\Delta\alpha) - \cos(2\Delta n+2b-2\theta)\}$$

We can define $\theta' = \Delta b - \theta$, $I_0 = c\varepsilon_0 E_0^2$, the equation will become:

$$I = \frac{I_0}{2}e^{-2(\beta+\alpha)}\{\cosh(2\Delta\beta)\cosh(2\Delta\alpha) + \sinh(2\Delta\beta)\sinh(2\Delta\alpha)$$

$$- \cos(2\Delta n)\cos(2\theta') + \sin(2\Delta n)\sin(2\theta') \qquad (3.10)$$

Because the crossing angle, the amount of absorption and the birefringence is small, we can assume that:

$$\sin x \approx x, \sinh x \approx x, \cos x \approx 1 - \frac{x^2}{2} \text{ and } \cosh x \approx 1 + \frac{x^2}{2}$$

Using these expansions and neglect terms in fourth order of small quantities, we can get

$$I = I_0 e^{-2(\beta+\alpha)} \{\Delta\beta^2 + \Delta\alpha^2 + 2\Delta\beta\Delta\alpha + \Delta n^2 + (\theta')^2 + 2\Delta n\theta'\} \tag{3.11}$$

We define $\dfrac{I}{I_0} = \xi$ as the transmission rate when the two linear polarizers are polarized:

$$I = I_0 e^{-2(\beta+\alpha)} \{\xi + \Delta\beta^2 + \Delta\alpha^2 + 2\Delta\beta\Delta\alpha + \Delta n^2 + (\theta')^2 + 2\Delta n\theta'\} \tag{3.12}$$

Because the absorption coefficient $a(\omega)$ and the refractive index $n(\omega)$ are related by the Kramers – Kronig dispersion relation, we can write $n(\omega)$ in terms of the line-center dichroism Δa_0:

$$\Delta a(\omega) = \frac{\Delta a_0}{1+x^2} , \quad x = \frac{\omega_0 - \omega}{\gamma_s / 2} , \quad \Delta n(\omega) = \frac{\Delta a_0 x}{1+x^2} \tag{3.13}$$

Using equation (3.12) and (3.13), the line profile of the polarization signal can be written as:

$$I = I_0 e^{-2(\beta+\alpha)} [\xi + \theta'^2 + (\Delta\beta)^2 + 2\Delta\beta \frac{\Delta\alpha_0}{1+x^2}$$

$$+ 2\theta' \frac{\Delta\alpha_0 x}{1+x^2} + (\frac{\Delta\alpha_0}{1+x^2})^2 + (\frac{\Delta a_0 x}{1+x^2})^2] \tag{3.14}$$

The first three terms are the constant background which is independent of the laser frequency. The fourth term is the Lorentzian part and the fifth term describes the dispersion. The last two terms are squares of small values and they can be neglected.

From this equation we can see that if $\theta' = 0$, the dispersion term will vanish and only the background terms and the Lorentzian terms will be left. In our experiment, we use a power meter (Coherent LabMax TO) with a sensitive detector (LM-2) after the second polarizer, when the heatpipe is cold, and the pump laser is off, to make fine adjustments of the orientation of the second polarizer. At this time, θ' will be decreased to zero if we minimize the reading of the power meter by adjusting the second polarizer. Another way to cancel the dispersion term is to scan the polarization signal directly. By looking at the shape of the polarization signal we can tell if the dispersion term is canceled. Here it should be noted that the PMT can be damaged if too much of the probe laser beam is transmitted through second polarizer during the adjustment.

3.2.5 Conclusion: Advantages of Polarization Spectroscopy

For heavier molecules like Rb_2 and Cs_2, the density of rovibronic energy levels is very high in any electronic state leading to spectra that are hard to identify. With the tunable narrow bandwidth single longitudinal mode lasers, these advantages of the polarization spectroscopic technique are widely recognized. They are summarized below:

48

1. We achieve high spectroscopic resolution by using the polarization spectroscopic technique. Doppler broadening is one of the main factors that limit the resolution of spectra. The spectra generated by the polarization spectroscopic technique are Doppler free because only the molecules with zero velocity in the laser propagation direction can absorb photons from counter-propagating pump and probe laser beams. With the removal of Doppler broadening, the resolution of the spectra is increased. The linewidth of the polarization signal we obtained in our experiments is from 150 MHz to 250 MHz instead of around 1 GHz. The Doppler broadening varies with temperature, scanning range, buffer gas pressure and the type of sample molecule. Low argon gas pressure also contributes to the high resolution of our spectra. In our experiments the argon pressure was 1 to 3 Torr for Rb_2 and Cs_2.

2. The signal to noise ratio is high which leads to high sensitivity since the probe laser transmission signal is observed with nearly zero background. The polarization characteristics of the probe laser change when the linear polarized probe laser excites a transition that shares the same ground state as the pump transition. The small amount of resulting elliptic polarization of the probe laser is transmitted through the crossed polarizer and detected by a PMT against nearly zero background. Thus the spectral resolution is very high.

3. The high resolution and high sensitivity polarization of spectroscopic technique make the accurate assignment of the spectra possible. The spectra of Rb_2 and Cs_2 dimers are complicated because many energy levels of the Rb_2 and Cs_2 are highly perturbed and the density of rovibrational levels is high. However, the survival of molecular orientation in

collisions can be used to extend the automatic parent (R,P) line assignments to the collisional components, which mitigates the assignment problems to a large degree and enhances the yield of the experiment a great deal. More than 2000 distinct spectral lines were resolved in our Rb_2 polarization experiment and 881 of them were identified [21]. More than 300 spectral lines were identified in our Cs_2 polarization experiment. Additional identificatons are in progress using fluorescence decay to the ground state, leading to additional probe signal assignments [20].

CHAPTER 4

EXPERIMENT

4.1 Introduction

It is well known that an alkali atom with Z electrons can be treated theoretically as a core consisting of the nucleus and Z-1 electrons, with one valence electron moving around them. Therefore, each alkali dimer molecule has only two valence electrons. The simplicity of the electronic structure is one of the reasons that alkali molecules have been studied extensively during the last century. With the recent development of ultra – cold atomic trapping techniques and the progress on Bose Einstein condensates [1,3,5], the interest in the study of diatomic alkali dimer molecules has increased again.

4.2 The Description of the Equipment Used in the Experiments

4.2.1 Lasers

A laser is an optical oscillator that emits light in a narrow, intense, low divergence monochromatic beam with a well defined wavelength. The laser was first invented in the

1960s and it has been used widely in scientific research, in medical applications, industry and military since then. The word *laser* stands for Light Amplification by the Stimulated Emission of Radiation.

There are three essential elements for each laser: the pump, the laser medium and the resonator. There are many kinds of lasers, including gas lasers, dye lasers, metal vapor lasers, solid state lasers and semiconductor lasers.

Dye Laser and TiSapphire Laser

In our the polarization spectroscopy set-up, a tunable single longitudinal mode (Coherent model 699 -29) ring dye laser was used as a pump laser, and a tunable single mode (Coherent model 899 – 29) TiSapphire laser served as the probe laser in both the Rb_2 and Cs_2 experiments. Each of them is equipped with an internal Coherent Autoscan wavemeter, which is used to measure the frequency of the output laser beam with the same computer control used to scan the laser. Each of the two lasers were pumped by a Coherent Verdi V10 solid state laser, which produces a laser beam at 532 nm wavelength with 10W maximum output power.

An infrared sensor card (Model F- IRC1) from Newport helped to trace the invisible infrared TiSapphire laser beam. More details of the dye laser and TiSapphire laser can be found in their laser manuals.

In order to create an optimal overlap region for the pump and probe lasers in the polarization experiment, we attached a razor blade to a translation stage and used this home made assembly to measure the beam waist w of the laser beams. We recorded the readings d_{75} and d_{25} of the micrometer screws when 75 percent and 25 percent of the laser beam passed through the razor blade. The beam waist w was calculated using the equation

$$w = 1.49(d_{75}-d_{25})$$

This method works if the laser beam has a Gaussian TEM0,0 profile, which can be verified using the method by Skinner and Whitcher [17].

4.2.2 Heatpipe Oven

The Rb and Cs metals were loaded at the center of a five-arm heatpipe oven in our polarization spectroscopy experiments. The heatpipe oven technique was first introduced by Vidal and Cooper [18] in 1969.

The pressure of the argon buffer gas inside the heatpipe oven was 1 to 3 Torr and at the end of each heatpipe oven arm there is a glass window which is sealed by a rubber O-ring. The Cs or Rb metal inside the heatpipe oven formed a vapor when the arms and the center of the heatpipe oven were heated by the Lindberg Model 50101 heaters. The region close to the heatpipe windows was cooled by water running through cooling coils on the outside of the heatpipe. The metal vapor diffused from the center of the heatpipe

oven and condensed in the cooler region. The condensed vapor then returned to the center of the heatpipe oven through capillary action created by several layers of stainless steel mesh loaded in each arm. Besides protecting the windows from being coated with metal, this design of the heatpipe oven makes the continuous evaporation and condensation of the metal vapor possible.

  The heatpipe oven can operate in either the "heatpipe" mode or the "oven" mode. The argon gas is excluded from the center part of the heatpipe oven when the metal vapor pressure is equal to the argon vapor pressure. This condition is called the "heatpipe" mode. In the "oven" mode, the pressure of the metal vapor is less than the pressure of the argon gas, and the two kinds of vapors mix with each other at the center of the heatpipe oven.

  We used a thermal probe to estimate the temperature of the metal vapor inside the heatpipe oven. More precise temperature can be obtained by measuring the full width at half maximum (FWHM) of the Doppler broadened pump laser induced fluorescence profile of the alkali metal dimer molecule. The expression for the temperature is

$$T = \frac{(\frac{\Delta\omega c}{2\omega_0})^2 m_0}{2(\ln 2)k} \qquad (4.1)$$

where $\Delta\omega$ is the FWHM value of the pump laser LIF profile in GHz, ω_0 is the laser frequency at the peak of this profile in the unit of GHz, c is the speed of light, m_0 is the mass of the dimer molecule in kg, and k=1.38*10^{-23} J/k is the Boltzmann constant. It is

important that the laser power has to be kept low enough in the Doppler profile scan to avoid saturation broadening, which would lead to an erroneous temperature reading.

4.2.3 Photomultiplier Tube Detector (PMT)

Photomultipliers (PMT) were used in our lab for detecting fluorescence or polarization signals. The wavelength response of the PMT depends on the model. The PMT is based on the photoelectric effect. We apply a high voltage to the PMT cathode usually from -300V to -800V according to the intensity of the signal we were detecting. The anode was kept at ground voltage. The photoelectrons emitted from the cathode were accelerated towards the anode through a dynode chain, each releasing additional electrons resulting in a current at the anode. The number of photoelectrons is multiplied at each subsequent dynode. We used a Hamamatsu a R928 in the Rb_2 experiment. Its operational range is from 185 nm to 900 nm, with peak sensitivity at 400 nm. To reduce thermal noise, the photomultiplier tube used for detecting resolved fluorescence was the SPEX 1404, which was cooled by a Products for Research (model number TE177RF005) cooling system. This was important for detecting weak signals in the photon counting mode.

4.2.4 BOMEM DA8 FTIR

FTIR stands for Fourier transform Infrared spectroscopy. Before introducing the Bomem DA8 FTIR interferometer, let us consider the concept of the Fourier transform. The Fourier transform of a function $f(x)$ can be defined by:

$$F(\sigma) = \int_{-\infty}^{\infty} f(x) e^{-i2\pi\sigma x} dx \qquad\qquad (4.2)$$

the inverse transformation *f(x)* can be reconstructed by:

$$f(x) = \int_{-\infty}^{\infty} F(\sigma) e^{i2\pi\sigma x} d\sigma \qquad\qquad (4.3)$$

Using the Euler formula $e^{ix} = \cos x + i\sin x$, the Fourier transform can be separated into real and imaginary components:

$$\mathrm{Re}[F(\sigma)] = \int_{-\infty}^{\infty} f(x)\cos(2\pi\sigma x) dx$$

$$\qquad\qquad (4.4)$$

$$\mathrm{Im}[F(\sigma)] = \int_{-\infty}^{\infty} f(x)\sin(2\pi\sigma x) dx$$

In spectroscopy the Fourier transform relates the time domain and the frequency domain. The Bomem DA8 FTIR is basically a Michelson interferometer. Michelson first used such a device with Morley to demonstrate that the ether did not exist **[12]**. Figure 4.1 is a simple sketch of the Michelson interferometer. It is composed of a beam splitter, a compensator, a fixed mirror and a moving mirror. The input beam is directed onto a beam splitter. One beam travels to a fixed mirror and the other beam travels to a moving mirror which is driven by a motor. The two reflected beams recombine at the beam splitter. The path difference of the two beams varies as the movable mirror moves continuously and the two beams interfere with each other constructively and destructively. A compensator is placed in one arm to make sure that the initial path difference is zero.
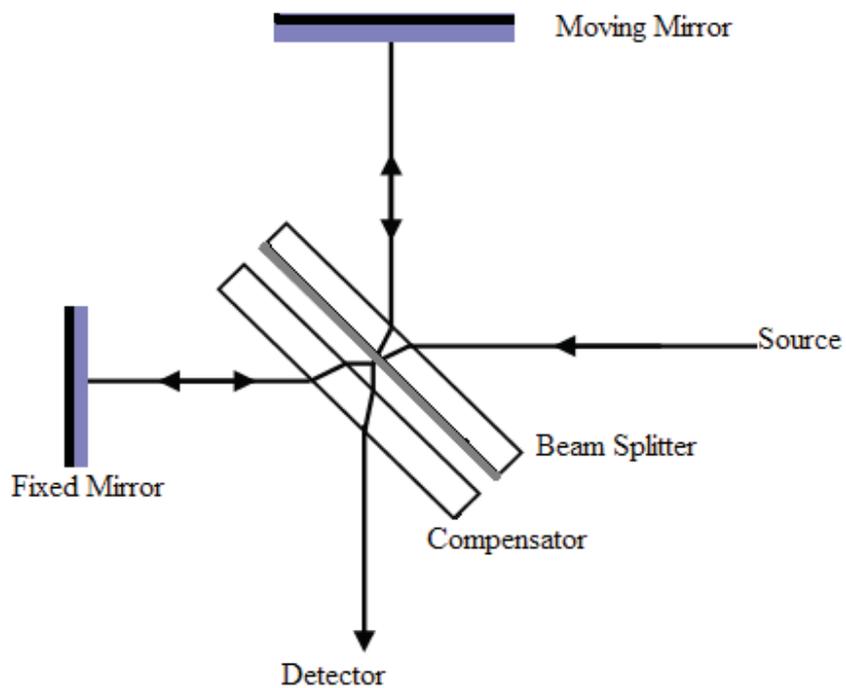

Figure 4.1 Michelson interferometer applied in the Bomem FTIR spectrometer. The incoming beam is split into two beams with equal intensity by the beam splitter. One beam is reflected by a moving mirror, and the other is reflected by a fixed mirror. The two reflected beams interfere at the beam splitter, and the interference pattern is detected. The compensator ensures that the two beams are in phase when the moving mirror is at the starting position.

The recombined signal is detected inside the Bomem interferometer, digitized and sent to the computer, which performs a Fourier analysis of the data. The light absorption/fluorescence intensity for each mirror position is function $f(x)$ and its Fourier transform $F(\sigma)$ represents the amplitude of each constituent sinusoid of wavenumber σ.

Figure 4.2 shows the optical configuration of our Bomem interferometer. From the discussion above, we see that the acquisition of the Bomem FTIR spectrum involves three steps:

First, the fluorescence beam generated from the heatpipe needs to enter the Bomem interferometer. To achieve this, the fluorescence is focused onto an optical fiber which transmits the light to the entrance port of the Bomem. The location of the fiber is carefully adjusted by a translation stage using an optical alignment procedure that involves sending a parallel beam of light through the interferometer in the reverse direction. The incoming beam is split by the beam splitter inside the Bomem, and the moving mirror creates the changing beam path difference. The interference pattern of the two beams is called the interferogram.

Second, the interferogram is detected by the detector inside the Bomem. After this, the measured interferogram signal is digitized and sent to the computer. The computer performs a Fourier analysis to transfer the interferogram into the spectrum. The longer the path that the moving mirror scans, the better the resolution. In the DA8 Bomem design the moving mirror can travel 2 meters, and the highest resolution that can be achieved is 0.016 cm^{-1}.
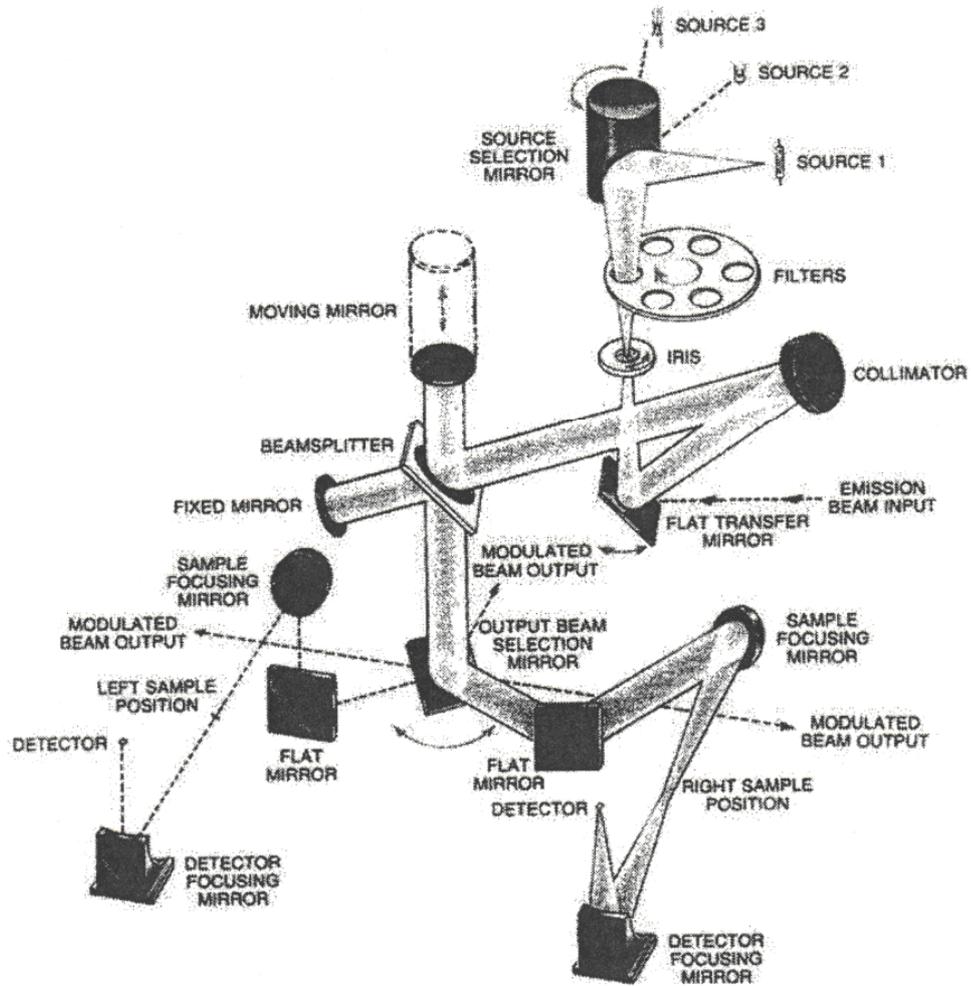

Figure 4.2 The Bomem DA8 series optical configuration.

The Bomem FTIR interferometer has some obvious advantages:

1. The built-in HeNe laser has a stable and accurate frequency. It acts as a calibration standard, which makes the Bomem interferometer internally self calibrated.

2. Because the Bomem FTIR interferometer obtains the light with all wavelengths simultaneously instead of individually, the time needed for it to finish a scan is much shorter, and the experimental conditions are much less likely to change during the scan.

3. The random noise can be significantly reduced by taking multiple scans which increases the signal to noise ratio.

The Bomem FTIR interferometer is a practical and accurate instrument to calibrate the frequency of laser beams and to acquire resolved fluorescence scans with very high resolution in the infrared spectral region.

4.2.5 Dual – Grating Monochromator (Spex 1404)

Another spectrometer used in our experiments to collect resolved fluorescence scans was the SPEX 1404, 0.85m dual-grating monochromator. The maximum spectral resolution of the Spex 1404 is 0.045A, which corresponds to $0.129cm^{-1}$ at $\lambda = 590nm$. Its absolute accuracy is $0.2cm^{-1}$ due to the stepping motor based grating angle control. The dispersion equation for the diffraction grating is:

$$d(\sin\theta_i + \sin\theta_r) = m\lambda \tag{4.5}$$

where d is the space between each groove, θ_i is the incident angle, θ_r is the diffraction angle, m is the diffraction order, λ is the wavelength. From this equation we see that the diffraction angle is wavelength dependent. When the servomotor controlled by the computer adjusts the position of the gratings with a chosen step size, the intensities of the various wavelength components in the incident beam at each wavelength are detected by the PMT which is attached to the exit slit assembly of the instrument.

Hongmin Chen and colleagues analyzed the $^7\text{Li}_2$ OODR resolved fluorescence spectra with a Spex 1404 double grating monochromator to study the polarization dependence and wavelength response of the monochromator. They detected fluorescence from the back, side and top of the heatpipe oven windows which contained $^7\text{Li}_2$ vapor. The reflection efficiency curves of the P, Q and R fluorescence lines were obtained. Details of this work can be found in reference [4].

Figure 4.3 shows an example of a scan obtained with the SPEX 1404 spectrometer. It shows the fluorescence from a $C^1\Pi_u \leftarrow X^1\Sigma_g^+$ pump transition. We can confirm the rotational quantum numbers of the terminal levels of the pump transition (J'' and J') by comparing the resolved fluorescence pattern to the known rotational energy level spacing from the ground state.
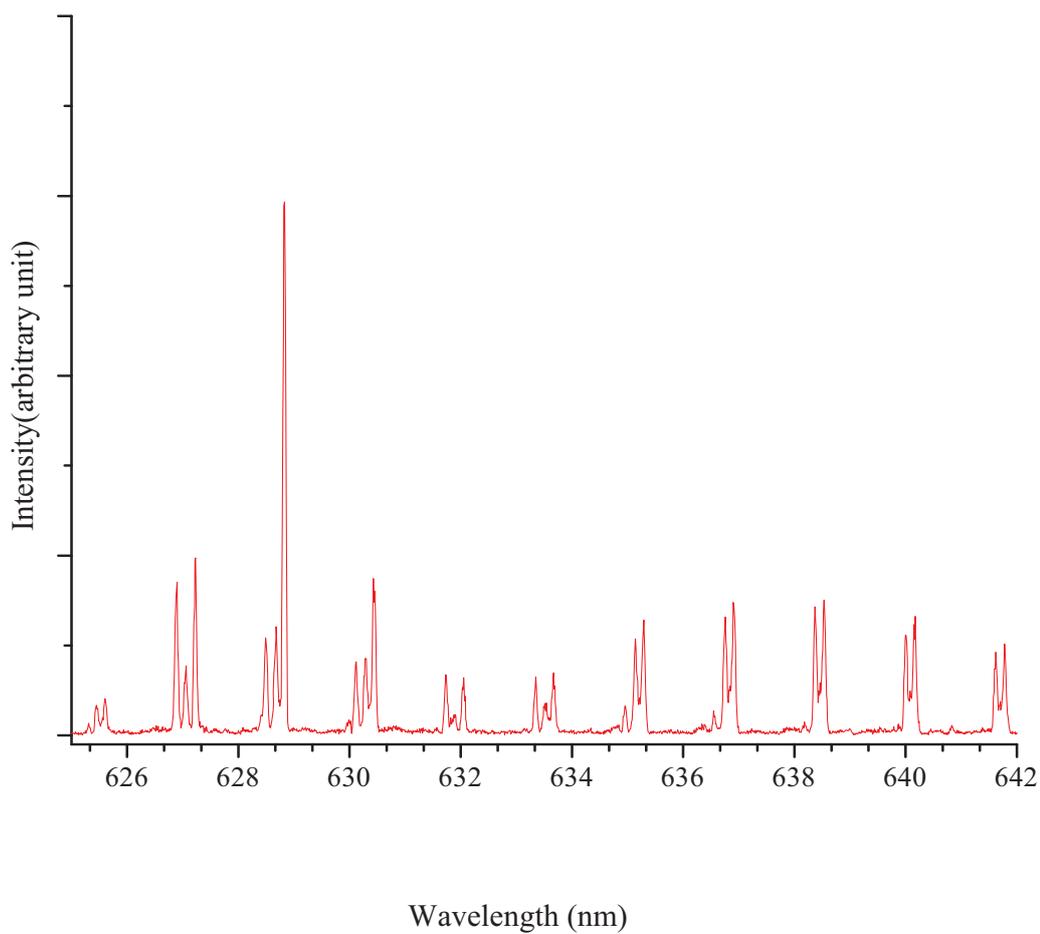

Figure 4.3 An example of the resolved fluorescence scan by SPEX 1404 spectrometer, which was used to confirm the pump transition in the Cs_2 polarization spectroscopic experiment.

4.2.6 Burleigh WA-1600 Wavemeter

A Burleigh 1600 wavemeter was used in our polarization experiments to measure the frequency of the TiSapphire laser when the frequency of the laser beam was outside the range of the Uranium lamp [14] used to calibrate the wavelength using optogalvanic spectroscopy. The absolute accuracy of this Burleigh 1600 wavemeter is 0.04 cm^{-1}. We used a single mode fiber to transmit the laser beam into the wavemeter. Figure 4.4 is a simple schematic of the Burleigh wavemeter. The wavemeter has two important components: a Michelson interferometer and a built-in He-Ne laser. The Michelson interferometer splits the input beam and generates interference fringes. The He-Ne laser with accurate well known frequency is the reference beam.

When the moving mirror of the Michelson interferometer moves a distance d, the number of fringes produced is given by:

$$m\lambda = 4n_\lambda d \tag{4.6}$$

where m is the number of fringes produced, λ is the wavelength of the input beam and n_λ is the refractive index of air for wavelength λ. A built-in He-Ne laser is used as the reference beam to accurately measure the distance d. For the reference beam, we can write:

$$m_0\lambda_0 = 4n_0 d \tag{4.7}$$

Combining the two equations, we get:

$$\lambda = \left[\frac{m_o}{m}\right]\left[\frac{n_\lambda}{n_o}\right]\lambda_o \tag{4.8}$$
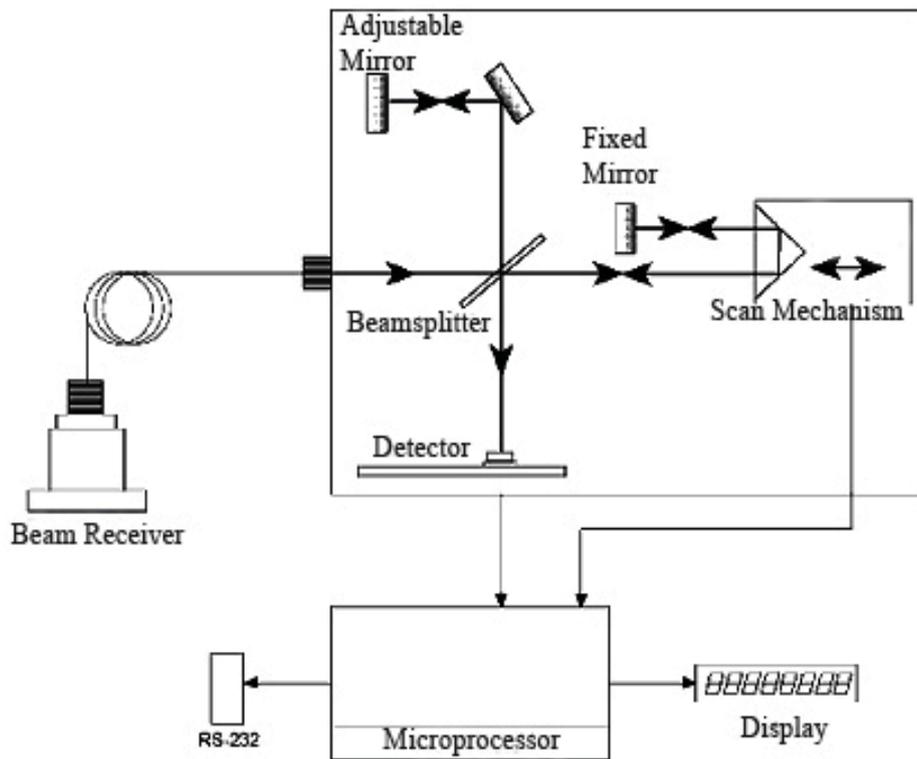

Figure 4.4 A simple schematic of the Burleigh wavemeter. The design is basically a

Michelson interferometer. The interference pattern is detected and transferred to the

microprocessor where it is analyzed to obtain the wavenumber. A stabilized single

frequency He-Ne laser was used as reference The wavenumber is displayed digitally.

From this equation we see that the accuracy of the Burleigh wavemeter depends on the

ratio of the number of fringes of the He-Ne reference laser beam and the input laser

$\left[\dfrac{m_o}{m}\right]$, the ratio of the refractive indexes $\left[\dfrac{n_\lambda}{n_o}\right]$ and the wavelength of the reference

beam λ_0.

In order to determine systematic measurement errors, we measured the reading errors of

the Bomem and the Burleigh WA-1600 wavemeter at different spectral ranges based on

an optogalvanic calibration spectrum using the Uranium lamp and its Atlas of a calibrated

Uranium spectrum [14]. Table 4.1 lists the reading errors of the Bomem and the Burleigh

WA-1600 wavemeter.

Table 4.1 Reading errors of the Bomem and the Burleigh WA-1600 wavemeter. The average magnitude of the Burleigh wavemeter system error is 0.0217 cm^{-1} and the root mean square (rms) is 0.0247 cm^{-1}. The average magnitude of the Bomem system error is 0.0268 cm^{-1} and the rms error is 0.027 cm^{-1}.

Uranium Atlas (cm^{-1})	Burleigh (cm^{-1})	Bomem (cm^{-1})	Burleigh Error (cm^{-1})	Bomem Error (cm^{-1})
11041.3737	11041.334	11041.3438	0.0397	0.0299

4.3 Rubidium and Cesium Density

The densities of the Rubidium and Cesium dimer molecules can be estimated in general as a percentage of atomic density (4 to 5%). Nesmeyanov introduced a formula to calculate the vapor pressure of different chemical elements [13]:

$$\lg p_{mm} = A - \frac{B}{T} + CT + D \lg T \tag{4.9}$$

Here p_{mm} is the pressure of the atoms or molecules in Torr, T is the temperature inside the heat-pipe oven in K, and A,B,C,D are constants . Table 4.2 gives the values of the constants for Rb, Rb_2, Cs, and Cs_2.

Table 4.2 The constants in Nesmeyanov's formula for different species.

Species	A	B	C	D
Rb	15.88253	4529.635	0.00058663	-2.99138
Rb_2	41.2753	7226.316	0.00333213	-11.8551
Cs	8.22127	4006.048	0.00060194	-0.19623
Cs_2	18.22054	6064.472	0.00009016	-3.45395

After measuring the pressure of the atomic species or the molecule of interest, its density can be obtained from the ideal gas law:

$$n = \frac{P}{kT} \tag{4.10}$$

Here n is the density of the atom or molecule interested, k=1.386504E-23 J/K.

Table 4.3 Temperature, pressure and densities of the Rb_2 and Cs_2 dimers.

Dimer	T(K)	P(Torr)	n(cm^{-3})
Rb_2	480	8.112E-5	1.62E12
Cs_2	550	5.94E-3	1.03E14

4.4 The Experiment

4.4.1 Summary of the Experiment

We applied collisional orientation transfer facilitated V-type optical-optical double-resonance (OODR) polarization spectroscopy technique to study the A/b complex states of Rb_2 and Cs_2. This technique is well suited to observe selected transitions in the congested spectra of Rb_2 and Cs_2. Due to collisional transfer of orientation, a series of well-separated spectral lines associated with nearby levels that were oriented and polarized were generated. A circularly polarized pump laser beam, tuned to a chosen transition, creates an anisotropic distribution of magnetic sublevel populations (net orientation) in ground state rovibrational levels. The counter-propagating probe laser

beam is linearly polarized, which can be considered to be made up of equal left and right components of circular polarization. When the probe frequency is tuned to a transition sharing either level with the pump transition, the orientation created by the pump causes the two components different absorption coefficients (circular dichroism) and different indices of refraction (circular birefringence). As a result, the two components no longer sum to the initial linear polarization when the probe beam exits the heat pipe oven. Instead, the beam has a slight elliptical polarization and some fraction of it is transmitted through a final crossed linear polarizer before reaching the detector.

4.4.2 Details of the Experiments

The experimental setups for the Rb_2 and Cs_2 polarization experiments were similar. As shown in Figure 4.5, the Rb_2 or Cs_2 metal was loaded at the center of a five-arm heat-pipe oven, which was kept at a temperature of 480 K for the Rb_2 experiment and 550 K for the Cs_2 experiment, with 1 to 3 Torr of argon buffer gas pressure. A CR-699-29 tunable single mode laser from Coherent with DCM dye was used as the circularly polarized pump laser in the Rb_2 polarization experiment, tuned to known $B^1\Pi_u\,(2,\ 70) \leftarrow X^1\Sigma_g^+\,(0,\ 71)$ transition. In the Cs_2 polarization experiment, a Kiton red 620 dye laser served as pump laser. Multiple $C^1\Pi_u\,(v',\ J') \leftarrow\ X^1\Sigma_g^+\,(v'',\ J'')$ pump transitions were used during the experiment to get a wider range rotational levels with different J values per vibrational level. A linearly polarized CR-899-29 Ti-Sapphire laser served as the probe laser for both of the experiments. The pump and probe lasers were counterpropagating and overlapped at the center of the heatpipe oven with a crossing
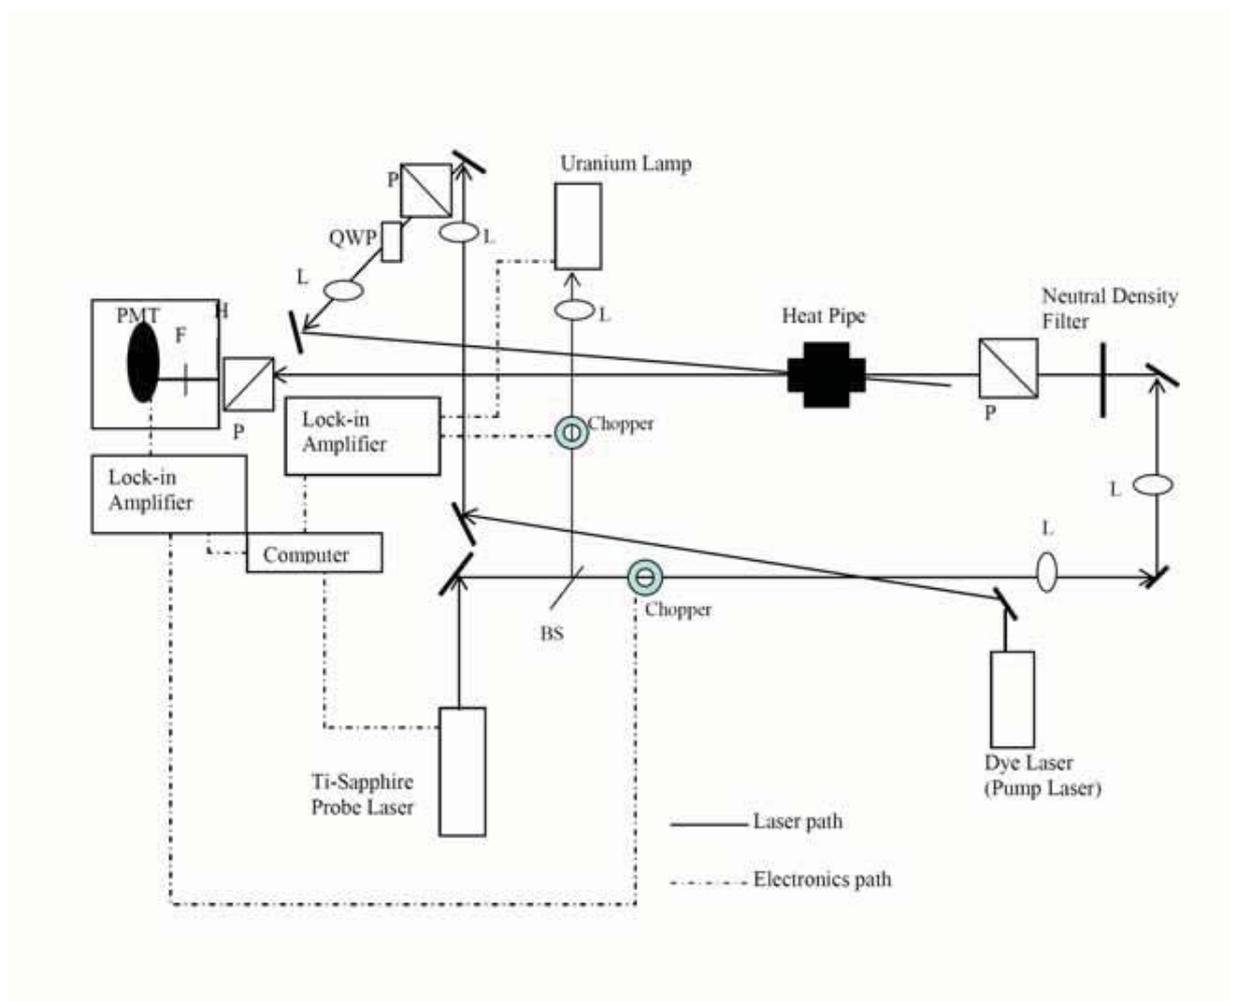

Figure 4.5 Schematic diagram of the Rb_2 and Cs_2 polarization spectroscopy experimental setup. BS, beam splitter; L, lens; PMT, photomultiplier tube; P, linear polarizer; QWP, Babinet-Soleil compensator; H, pin hole; F, filter.

angle that was minimized so as to maximize the overlap area. The spot sizes (defined as the radius at $1/e^2$ intensity) of the pump (1.2 mm) and probe (0.9mm) laser beams in the interaction region were measured with a razor blade technique [17]. Two lenses were placed in the path of each laser beam for collimation inside the heat pipe oven.

A Glan Thompson linear polarizer and a $\lambda/4$ Babinet-Soleil compensator from Karl Lambrecht Inc, Chicago were used to circularly polarize the pump beam. Two linear polarizers in the probe laser beam path (one before and one after the heat pipe oven) were oriented with their transmission axes at a 90 degree angle for maximum extinction of the probe laser when it was off resonance. A power meter (Coherent LabMax TO) with a sensitive detector (LM-2) placed after the second polarizer was used to make fine adjustments of the orientation of the second polarizer to create an optimal extinction ratio of 10^{-6} (and then removed for data acquisition). The observed ratio includes effects of window birefringence and circular dichroism.

Wavelength (nm)
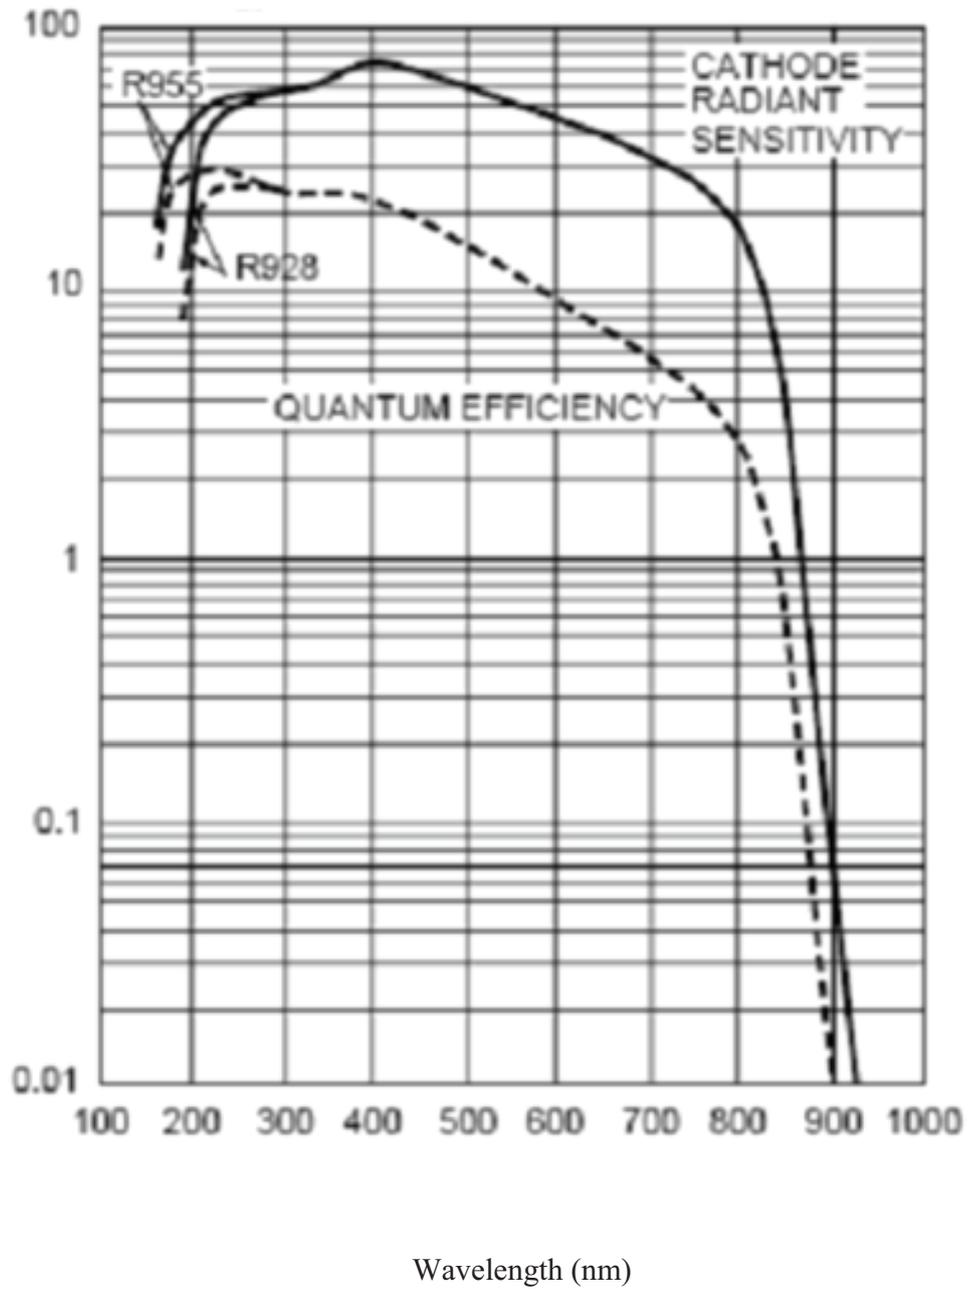

Figure 4.6 Spectral response curve of the R928 photomultiplier tube used in the Rb_2 polarization experiment.
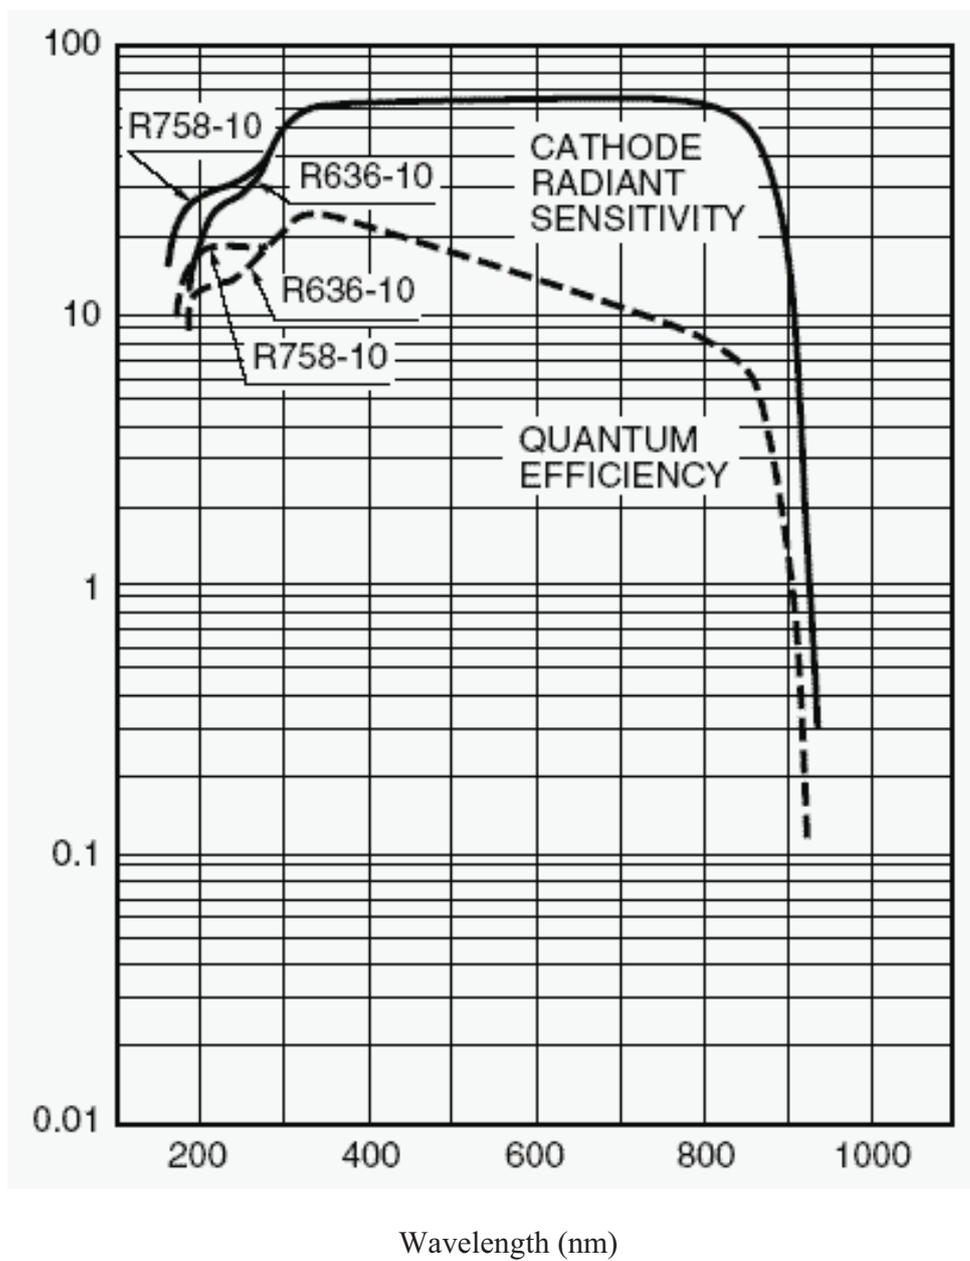

Figure 4.7 Spectral response curve of the R636-10 photomultiplier tube used in the Cs_2 polarization experiment.

A photomultiplier tube (Hamamatsu R928) which is sensitive to light in the range of 200nm to 850nm was used to detect the polarization signal in the Rb_2 experiment. Figure 4.6 gives the spectral response curve of the R928 tube. In the Cs_2 experiment, the TiSapphire scanned at a longer wavelength range than that in the Rb_2 experiment, so we chose the Hamamatsu R636-10 photomultiplier tube to detect the polarization signal. Its spectral response range is from 200 nm to 930 nm. Figure 4.7 shows the spectral response curves presented by Hamamatsu Photonics. To reduce the possibility that scattered light from the pump beam detected by the PMT detector, we placed 780 nm and 800 nm long pass filters before the PMT detector to block the scattered light.

The output from the PMT was amplified using a lock-in amplifier (Stanford Research Systems SR 850) for phase sensitive detection. The pump laser was modulated at a frequency of 980 Hz using a mechanical chopper (Stanford Research Systems SR 540). The pump laser was calibrated using an Iodine Atlas [8], with corrections from [9]. The estimated accuracy was 0.004 cm^{-1}. The Ti:Sapphire laser was calibrated by comparing optogalvanic spectroscopy signals from a Uranium lamp to line positions in the Uranium Atlas [14] when it scanned above 11000 cm^{-1}. The listed wavenumbers in the Uranium Atlas are accurate to ±0.003 cm^{-1}. At least one Uranium spectral line was included in each of the spectral scans for calibration purpose. A Burleigh 1600 wavemeter and BOMEM DA8 FTIR were used to calibrate the Ti:Sapphire frequency when it scanned below 11000 cm^{-1}.

Because the Franck-Condon factors for the Cs_2 pump transitions were weaker by a factor of 100 than for the Rb_2 polarization spectrum, the signal-to-noise ratio was smaller,

and fewer collisional satellites were observed in the Cs_2 polarization spectroscopy than with Rb_2 ($\Delta J \leq 12$ rather than ≤ 58). Also, due to spectral congestion, the C- X pump transitions were difficult to isolate. Collisional lines helped us to expand the data field but can only be observed if orientation is transferred from the ground state level labeled by the pump laser to a neighboring level. A quantitative study of the transfer of population and orientation in collisions of NaK molecules with argon and potassium atoms has been carried out and reported in [19] and [20]. These references discuss the transfer of orientation following the discussion of Ref. [7] and also present a complete analysis of polarization spectroscopy line shapes, extending the textbook presentation in [6].

4.5 The Pump Transitions

4.5.1 Franck-Condon factors (FCF) of the Pump Transitions

In a transition, the vibrational overlap of the wavefunction between the the initial and excited state rovibrational levels is called the Franck-Condon factor (FCF). The FCF or the transition dipole moment matrix element can be used to predict the strength of a rovibronic transition. To select pump transitions with reasonable intensity for our polarization experiments, it is necessary to know the FCF's.

The FCF's can be calculated by solving the radial Schrodinger equation of the involved states if the potential curves of both of the states are known. We used the LEVEL program written by Dr. Le Roy [11] from University of Waterloo for the B-X system of the Rb_2 dimer [16] and the C-X system of the Cs_2 dimer [2].

4.5.2 Pump Transition for the Rb$_2$ Polarization Spectroscopy Experiment

For the pump laser transition in the Rb$_2$ A~b global deperturbation study a DCM dye laser was chosen based on a good FCF within the B-X system. The laser frequency 14736.184 cm^{-1} used for the main pump transition $B^1\Pi_u(2,70) \leftarrow X^1\Sigma_g^+(0,71)$ also overlapped accidentally with the $B^1\Pi_u(2,85) \leftarrow X^1\Sigma_g^+(0,84)$ transition. The Franck-Condon factors of these transitions were 0.2139 and 0.2126, respectively.

4.5.3 Pump Transitions for the Cs$_2$ Polarization Spectroscopy Experiment

The tunable single mode Coherent CR-699 ring dye laser with Kiton Red 620 dye was used as pump laser in the Cs$_2$ polarization spectroscopy experiment. We chose $C^1\Pi_u \leftarrow X^1\Sigma_g^+$ transitions as our pump transitions because the wavelengths of the transitions between these two electronic states fall into the lasing range of the Kiton Red 629 dye laser.

Several techniques of high resolution spectroscopy have been applied to the study of the $C^1\Pi_u \leftarrow X^1\Sigma_g^+$ transition. Kasahara *et al*. [10] determined the molecular constants of $C^1\Pi_u$ (v = 7 – 18) rovibrational levels from their high resolution spectra by the Doppler - free Optical - Optical Double Resonance (OODR) polarization technique.

Table 4.4 FCF table of the Cs$_2$ C-X states. The numbers listed in the table are the FCFs $\times 10000$.

15	0	0	0	1	5	21	69	173	308	507	291

They also found that a number of $C^1\Pi_u$ (v>12, J) levels were highly mixed with the $(2)^3\Pi_u$ levels. The mixed levels are not purely singlet or triplet. Due to spin – orbit perturbation, each perturbed level has a mixture of the singlet character and triplet character.

Raab *et al.* [15] used the Doppler- free polarization spectroscopy and Optical - Optical Double Resonance (OODR) to study the Cs_2 band system around λ=625 nm and recorded more than 2000 completely resolved rotational lines in the $C^1\Pi_u \leftarrow X^1\Sigma_g^+$ band system. Twenty six different $C \leftarrow X$ transitions (ground state $3 \leq v'' \leq 8$ and $52 \leq J''$ ≤ 121) were confirmed for the Cs_2 polarization spectroscopy experiment, and 20 of them served as pump transitions in the experiment. Table 4.4 gives the FCFs of the $C \leftarrow X$ transitions. These results guided us in choosing the right pump transitions. Table 4.5 is a list of the pump transitions we used in the Cs_2 polarization experiment.

Table 4.5 A list of the pump transitions that were used in the Cs$_2$ polarization spectroscopic experiment. Due to weak Franck-Condon factors from the ground state to the A/b perturbed state, we could only observe angular momentum changes up to $\Delta J_{max} = 12$ compared to $\Delta J_{max} = 58$ in the Rb$_2$ experiment. Multiple pump transitions were needed to increase the number of rotational satellite lines that could be observed.

CHAPTER 5

EXPERIMENTAL RESULTS

We have observed a large number of rovibrational levels of the A/b complex (consisting of the $A^1\Sigma_u^+$ and $b^3\Pi_u$ electronic states) in $^{85}Rb_2$ and Cs_2 using V-type optical-optical double resonance polarization spectroscopy. A circularly polarized laser was used as the pump laser and a linearly polarized laser was used as the probe laser.

5.1   Collision Induced Orientation Transfer

The main electric dipole rovibrational transitions from pump laser lower level with vibrational and rotational quantum number v", J" the transitions to the excited state rovibrational levels v', J' = J"-1 (P line) and v', J' = J"+1 (R line) for vibrational levels v' with good Franck-Condon factors. In addition to the *R, P* doublets, expected from a single pump laser, we have observed molecular orientation transfer based probe laser signals from a large number of collisionally populated rotational levels. For a homonuclear molecule these collisional satellite lines occur in steps of $\Delta J = \pm 2$ [1-5]. From Figures 1 and 3, it is obvious that collisional lines only appear when the difference of the rotational quantum numbers between the directly pumped 'parent' line and the collisionally induced lines is an even number $\Delta J = \pm 2, \pm 4, \ldots \pm 2k$ lines.   This is

because in homonuclear molecules like $^{85}Rb_2$ and Cs_2, only transitions that can preserve the symmetry with respect to an interchange of the nuclei are allowed which is consistent with the selection rules

$$a \leftrightarrow a$$

$$s \leftrightarrow s$$

This rule breaks down for heteronuclear molecules because the interchange of the nuclei breaks the symmetry of the wavefunction. S. Antonova *et al.* [6] observed $\Delta J = \pm 1$, ± 3, ... collisional satellite lines in their $^6Li^7Li$ spectra. But the intensity of these extra lines was weak, indicating a breakdown of the symmetric–symmetric (s-s) and antisymmetric - antisymmetric (a-a) selection rule in the $^6Li^7Li$ spectra. Thus, in the context of collisional energy transfer the $^6Li^7Li$ appears to be heteronuclear.

The satellite lines observed in our polarization spectra are due to collision induced transfer of population with anomalous magnetic sublevel distribution from the pump laser terminal levels to nearby energy levels. In these collisions the anisotropic distribution of population as a function of the magnetic quantum number M_J created by the circularly polarized pump laser survives in the collisional energy transfer. It is this additional portion of the population with angular momentum orientation in thermally populated rovibrational levels in the ground state that leads to probe laser signals. The rovibrational level populations generated in this manner by collisional energy transfer then served as additional ground state levels with molecular angular momentum orientation for new $A^1\Sigma_u^+ \leftarrow X^1\Sigma_g^+$ probe laser transitions. In Fig. 5.1 there are collisional satellite lines up to $\Delta J = -58$ (from J"=71 to J"=13) and $\Delta J = +18$ up to J"= 89 in steps of $\Delta J = \pm 2$, in $^{85}Rb_2$ [1-4]. The intensity of the collisional satellite lines becomes weaker the higher the

angular momentum change. Observation of such a large number of collisional satellite lines, that could be easily identified, with such a large change in the angular momentum ΔJ in steps of $\Delta J = \pm 2, \pm 4$ etc. in our polarization spectra was possible because of a high signal to noise ratio in our experiment. As a result, the collisional energy transfer signals revealed a lot of additional energy level information about the A/b perturbed state of Rb_2 beyond the expected parent R,P lines (see Fig. 5.2).

Collision induced energy transfer in polarization spectra has been observed previously. Teets *et al.* [7] obtained polarization spectra of Na_2 showing inelastic collisional transfer in 1976 by combining the methods of polarization spectroscopy and labeling of the pump laser lower level by using a circularly polarized pump laser. In this early work the inert gas pressure in the sample was a few hundred Torr, leading to collisional broadening of the polarization spectra and subsequent loss of resolution.

M.D. Rowe and A.J. McCaffery [8] observed inelastic collision- induced rotational transfer lines of the Li_2 $A^1\Sigma_u^+$ state with ΔJ values up to 18. C. Ottinger and M. Schroder [9] monitored collision – induced rotational transitions of the labeled $A^1\Sigma_u^+ \leftarrow X^1\Sigma_g^+$ transitions of Li_2. They applied semiclassical time–dependent perturbation theory to analyze their experimental data and were able to reproduce the relative magnitude of the measured cross sections, including the $+\Delta J/- \Delta J$ asymmetry, which matched well with the experiment. A theoretical analysis of this problem was presented by J. Derouard [10] for the experimental data obtained by references [11], [8]

and [9]. McCaffery and coworkers [12-15] demonstrated that the line-shapes of the collisional lines can be used to determine differential cross sections.

Collision induced energy transfer in the of the B state of Cs_2 was observed by U. Diemer *et al*. [16] in their polarization spectroscopy experiment. In the high resolution polarization spectroscopy study of the $B^1\Pi \leftarrow X^1\Sigma^+$ transition of $^{39}K^{85}Rb$ molecule, N. Okada et al. [17] observed six types of probe signals occurring in optical-optical double resonance spectroscopy, including the collision-induced transfer signals. More information about collision-induced orientation transfer can be found also in the work of S. Kasahara and coworkers [18-20].

More recently, C.M. Wolfe and coworkers [21] studied quantitatively the transfer of population and orientation in an inelastic collision study of NaK molecules with argon and potassium gas as perturbers. This heteronuclear diatomic system is more suitable for such a study than the homonuclear Rb_2 and Cs_2 dimer molecules since there are fewer electric dipole selection rules for the transitions between electronic states, such as the limiting 'gerade-ungerade' rule. A rate equation model was created to study the intensities of the collisional lines as a function of argon pressure and heatpipe oven temperature.

A common feature in all of the experiments mentioned above is that satellite lines due to collision – induced transfer of molecular orientation significantly expand the spectral range available experimentally.

5.2 The Experimental Spectra

5.2.1 The ^{85}Rb$_2$ Polarization Spectra

Figure 5.1 illustrates part of the spectra we obtained from our Rb$_2$ polarization experiment and shows Rb$_2$ ΔJ_{max} up to 58. The circularly polarized pump laser was tuned to the $B^1\Pi_u(2,70) \leftarrow X^1\Sigma_g^+(0,71)$ transition, and the probe laser was scanned over the various $A^1\Sigma_u^+(v',J') \leftarrow X^1\Sigma_g^+(0,J'')$ transitions from 11380 cm^{-1} to 12580 cm^{-1}. In order to also record the weaker signals, the lock-in amplifier sensitivity was adjusted for the strong parent lines $\Delta J= \pm 1$ to a less sensitive scale. The P (71) line and the R (71) line are the direct signals from the $B^1\Pi_u(2,70) \leftarrow X^1\Sigma_g^+(0,71)$ transition and the weaker lines are the satellite lines due to collision-induced orientation transfer. Figure 5.2 shows the observed data from our Rb$_2$ polarization experiment. The solid circles are the signals corresponding to the direct parent lines and the blank circles are signals due to collision-induced energy transfer.

In a global deperturbation analysis for the spin – orbit interaction performed by Dr. Tom Bergeman at Stony Brook, our polarization data was merged with data from several other sources. For the $A^1\Sigma_u^+$ and $b^3\Pi_u$ states, an analytic potential (Hannover form) was incorporated in a discrete variable representation of the Hamiltonian matrix for numerical energy-level calculations [22].

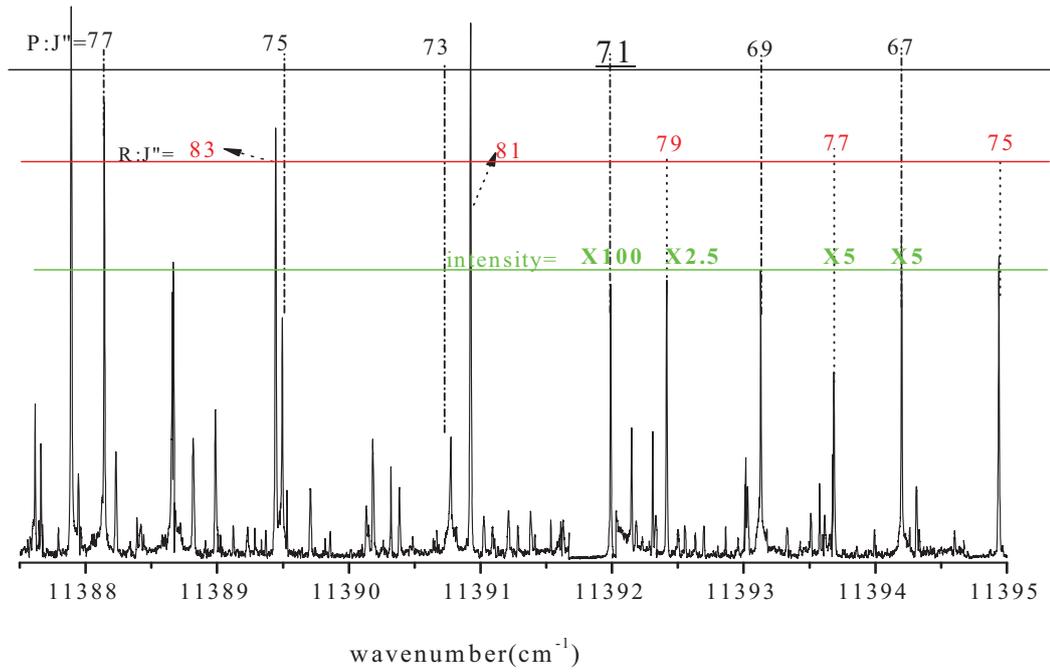

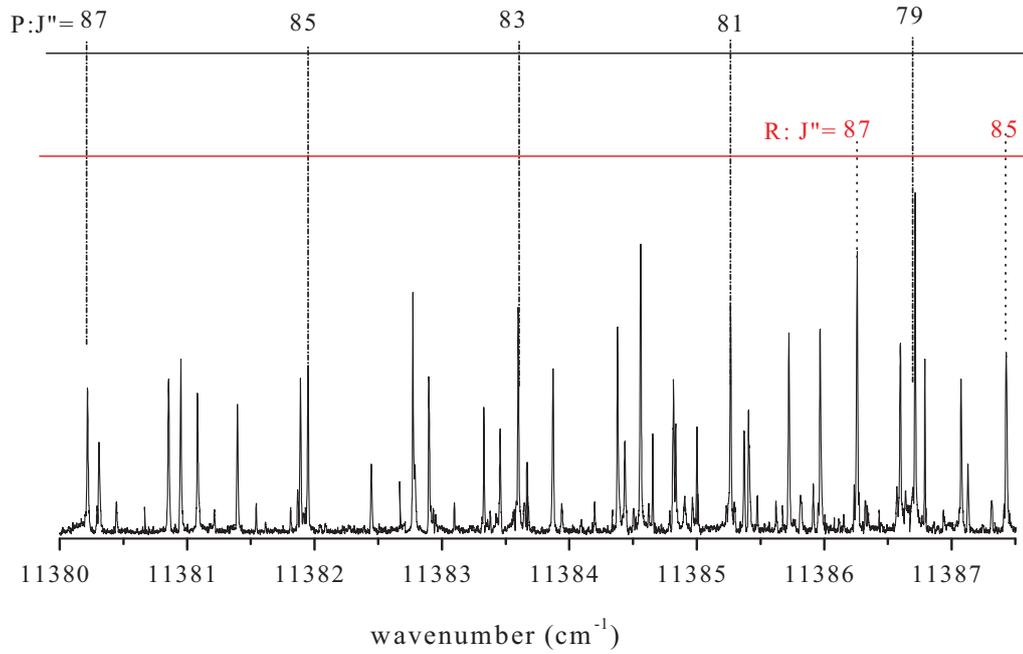

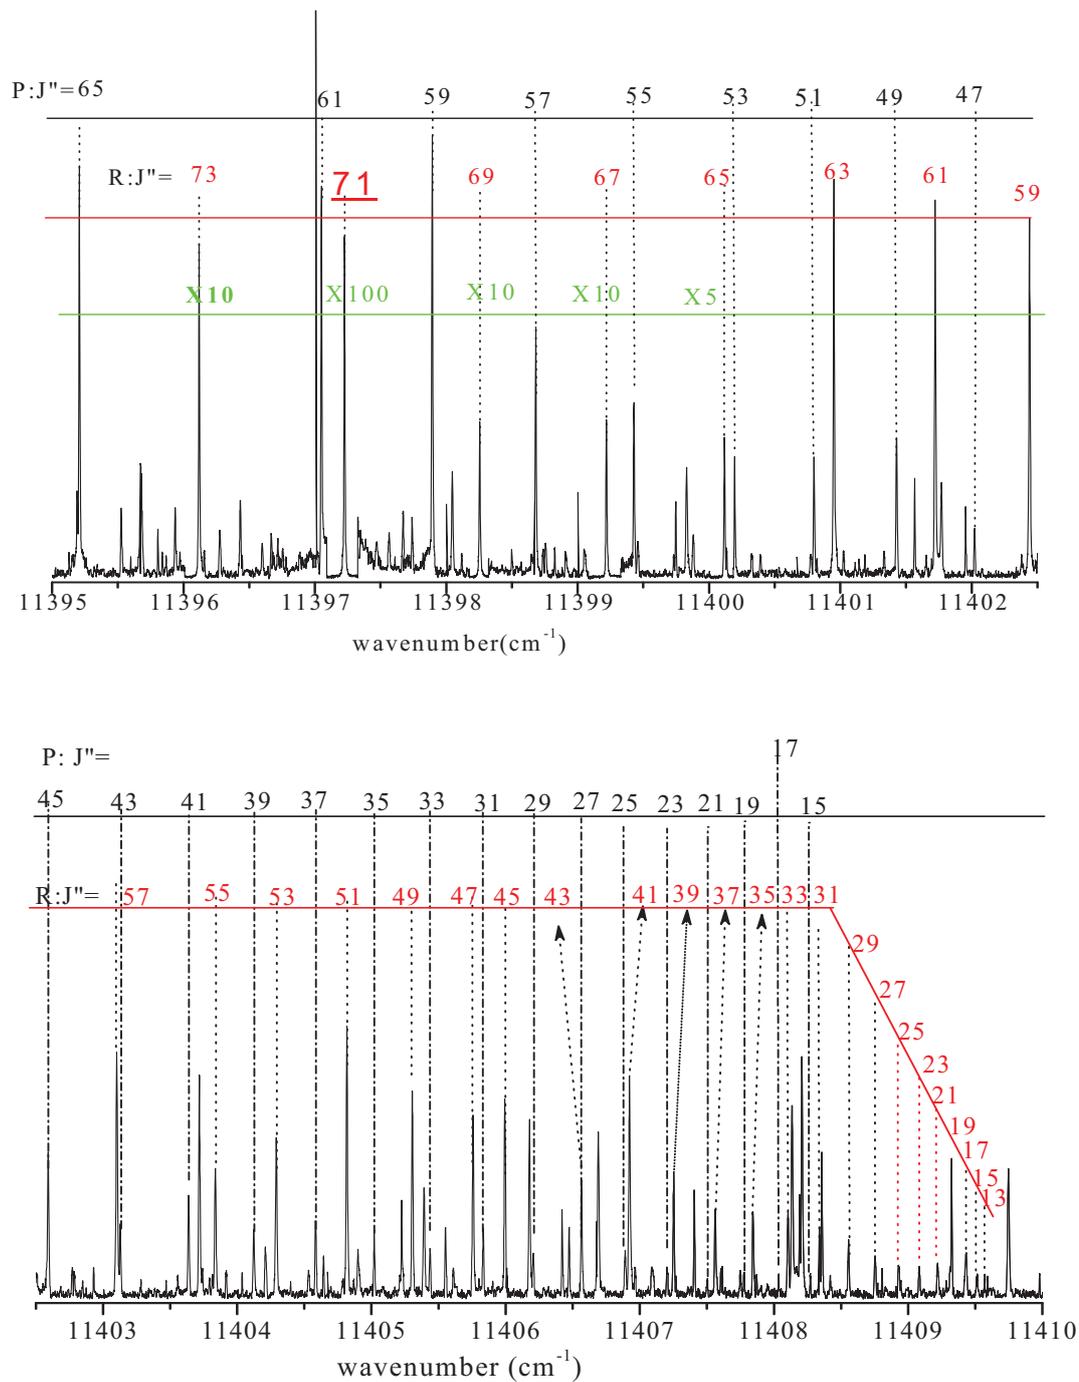

Figure 5.1 Rb$_2$ polarization spectrum with ΔJ_{max} up to 58. The pump laser was tuned to

the $B^1\Pi_u(v'=2, J'=70) \leftarrow X^1\Sigma_g^+(v''=0, J''=71)$ transition and the probe laser was

scanned over the various $A^1\Sigma_u^+(v', J') \leftarrow X^1\Sigma_g^+(v''=0, J'')$ transitions from 11380 cm^{-1} to

12580 cm^{-1}.
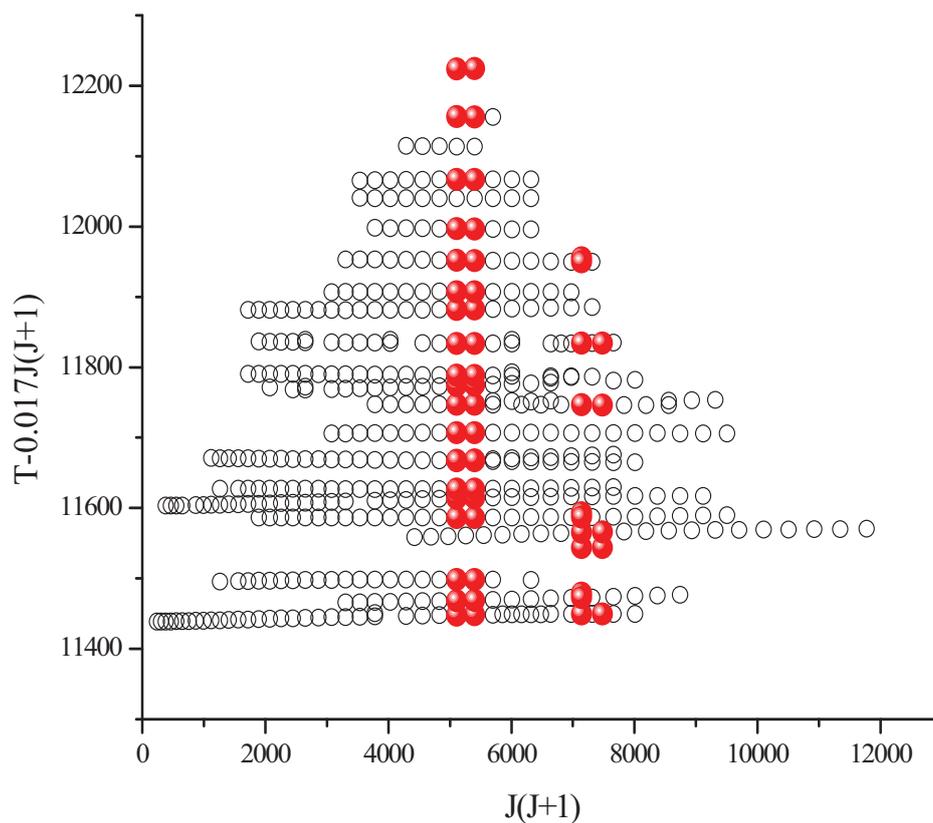

Figure 5.2 Observed energies of the Rb$_2$ A/b states. The rotational energy 0.017J(J+1) cm^{-1} has been subtracted from the energies. Here the rotational constant, which varies with the vibration quantum number, has been approximated by a constant value 0.017 cm^{-1}. The solid circles are the signals which do not involve collision-induced energy transfer. The blank circles are signals due to collision-induced energy transfer.

From our Rb$_2$ polarization spectra, 881 of the experimental peaks, including the direct P, R pairs and the collision induced satellite lines were identified.   For the same vibrational level, the P (J'' +1) line and R (J'' -1) lines of a certain upper state rotational quantum number $J'=J''$ should have the same term values even though they appear as distinct lines in the spectra due to different ground state term values. A total of 453 different term values were obtained from our identified (in terms of their rotational and vibrational quantum numbers) experimental probe laser scan peaks that originated from the pump laser lower level v$'' = 0$. The identified peaks of the Rb$_2$ polarization spectra are listed in the Appendix.   Because the $A^1\Sigma_u^+$ and $b^3\Pi_u$ electronic states of Rb$_2$ are highly perturbed, many rovibrational levels are of mixed singlet-triplet character. The quantum number 'n' is applied to denote different vibrational levels in the combined $A^1\Sigma_u^+$ and $b^3\Pi_u$ complex of states   instead of the traditional vibration quantum number 'v' in each state traditionally denoted by v$_A$ and v$_b$.

More than 1000 experimental spectral lines from the Rb$_2$ polarization spectra are still unidentified. Further analysis of the rest of the Rb$_2$ polarization is in progress. These transitions are likely to originate from higher lying ground state vibrational levels populated by fluorescence decay from the pump laser upper level (see Fig 5.3). In such levels the probe laser signals in the polarization spectroscopy originate from that the portion of the population added to the original thermal population that is both modulated by the pump laser mechanical modulation frequency and that has angular momentum orientation affected by the circularly polarized pump laser. The additional spectral line assignment analysis will yield information on the upper states both in the $A^1\Sigma_u^+ \sim b^3\Pi_u$

complex and also in excited states by vertical cascade type polarization double resonance at around 26,000cm^{-1}.
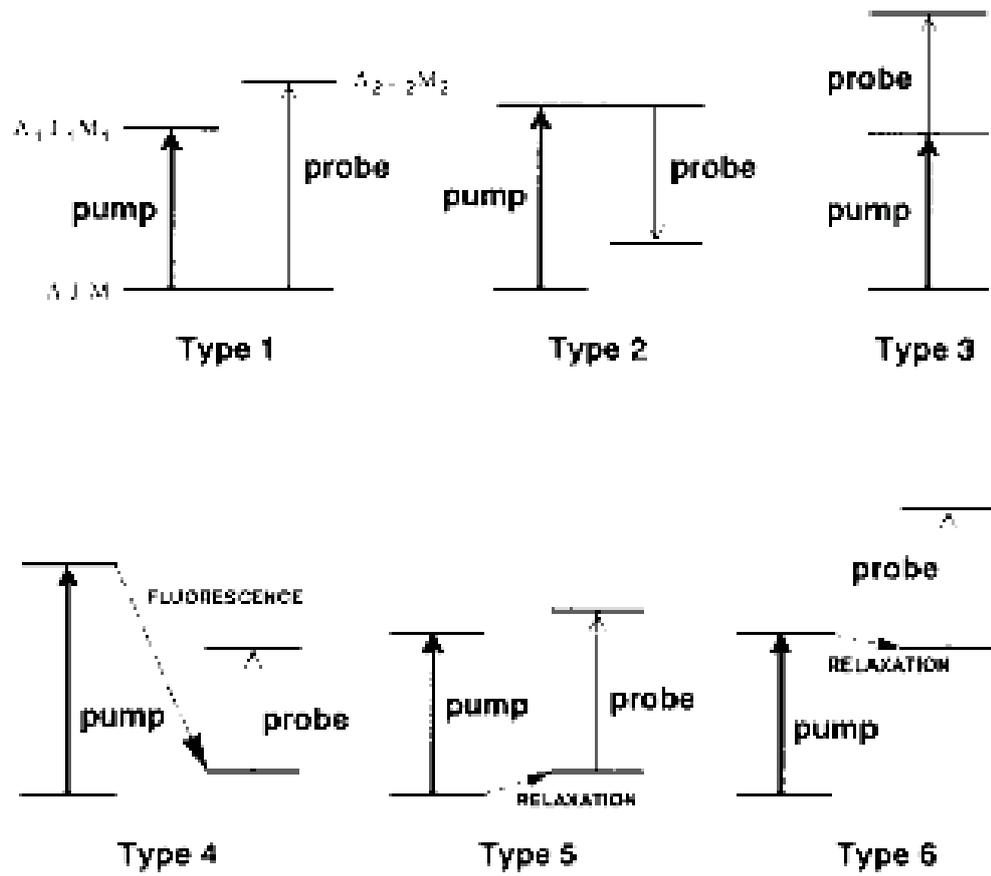

Figure 5.3 The six types of probe signals in OODR polarization spectroscopy[17].

5.2.2 The Cs$_2$ Polarization Spectra

Due to much weaker Franck – Condon Factors between the ground state $X^1\Sigma_g^+$ and the

$A^1\Sigma_u^+ \sim b^3\Pi_u$ perturbed complex of states, fewer collisional satellite lines were observed

in our Cs$_2$ experiment.   The difference of the rotational quantum number of the

collisional satellite lines from that of the main R,P lines in the Cs$_2$ spectra is much

smaller than for the Rb$_2$ spectra. Figure 5.4 shows part of the Cs$_2$ polarization spectra.   In

this scan, the $C^1\Pi_u(7,73) \leftarrow X^1\Sigma_g^+(6,74)$ transition and the $C^1\Pi_u(7,72) \leftarrow X^1\Sigma_g^+(6,73)$

transition were pumped simultaneously because the $C^1\Pi_u$ rotational energy level

structure of Cs$_2$ is very dense.   This made it very difficult to isolate pump laser

frequencies that would excite only one rovibronic transition. However, since the

polarization spectra were about hundred times weaker than in the ^{85}Rb$_2$ case, it was

necessary to isolate multiple pump transitions to get a broader range of rotational level

data for the region that had never been observed previously, leading to a gap in the global

deperturbation analysis of the spin-orbit interaction of the Cs$_2$ A~B complex of states.

The term values of the Cs$_2$ polarization data run from 11118 cm^{-1} to 11549 cm^{-1}.

Figure 5.5 shows the observed data from our Cs$_2$ polarization experiment (see also Fig.

6.1). The data partially fill in the energy gap of the $A^1\Sigma_u^+ \sim b^3\Pi_u$ complex of states of

Cs$_2$ that had been inaccessible to other research groups because of very poor Franck-

condon factors between the rovibrational levels within the ground state thermal

population and this energy region in the $A^1\Sigma_u^+ \sim b^3\Pi_u$ complex of states. The very high

signal to noise ratio of polarization spectroscopy made it possible to observe energy

levels in this gap region.

Cs$_2$ $A^1\Sigma_u^+ \leftarrow X^1\Sigma_g^+$ Polarization Spectrum
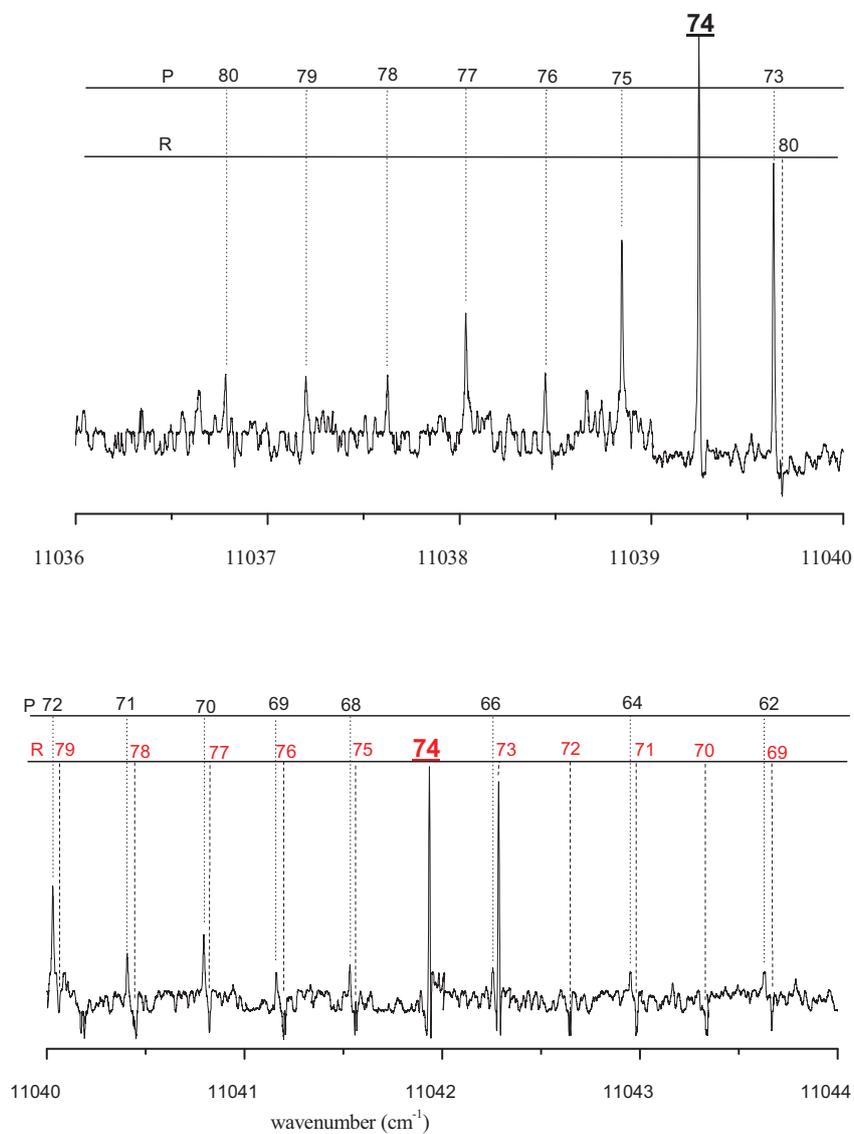

Figure 5.4 Cs$_2$ polarization spectroscopy signals. For this scan, both the

$C^1\Pi_u(7,73) \leftarrow X^1\Sigma_g^+(6,74)$ transition and the $C^1\Pi_u(7,72) \leftarrow X^1\Sigma_g^+(6,73)$

transition are pumped simultaneously.
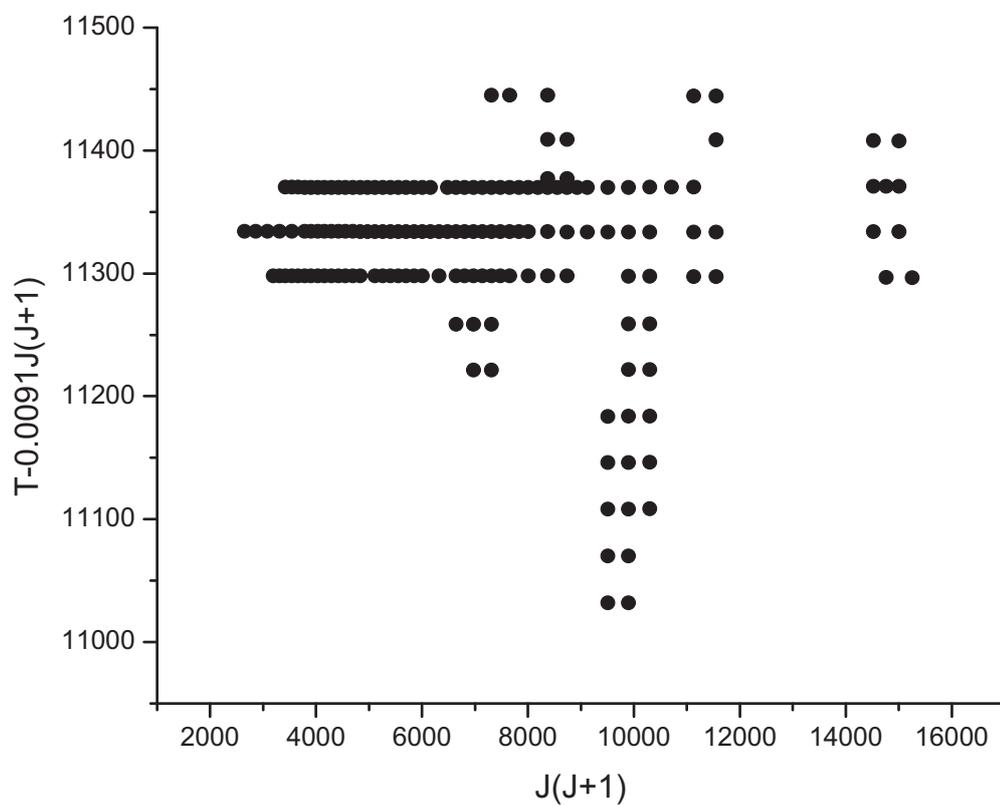

Figure 5.5 Observed energies of the Cs$_2$ A/b states. The rotational energy $0.0091J(J+1)$ cm^{-1} has been subtracted from the energies so as to approximately remove the rotational energy. The data partially fill the energy gap that was inaccessible to other groups.

5.2.3 Difference in the Collisional Satellite Spectra of Rb_2 and Cs_2

While collisional lines with significant difference in the rotational quantum number from the main lines up to $\Delta J = -58$ (and up to $\Delta J = +16$ for higher lying rotational levels) were identified in our Rb_2 polarization experiment. In our Cs_2 polarization experiment, the maximum number of collisional satellite lines corresponded to $\Delta J = -12$ (and up to $\Delta J = 6$ for higher lying rotational levels) and the signal to noise ratio was significantly lower than in the Rb_2 spectra despite all of our efforts to optimize it for the Cs_2 experiment. As can be seen from the comparison of the Franck – Condon factors for transitions of interest in Rb_2 and Cs_2, they play an important role in determining the intensities of the transitions. Figure 5.6 (a) shows the logarithm of the Franck- Condon factors for transitions between the v" =4 and v" = 5 ground states to A states of Cs_2, and Figure 5.6 (b) shows the logarithm of the Franck- Condon factors for transitions between the v" = 0 ground state to A states of Rb_2 calculated by Dr. T. Bergeman. The Franck- Condon factors for the Rb_2 are 100 times larger than for Cs_2.

Thermal Distribution

Another reason for the significant ΔJ difference between the Rb_2 polarization spectra and the Cs_2 polarization spectra is the thermal distribution of the ground state molecules. According to the Maxwell – Boltzmann distribution law, the number of molecules in each vibrational energy level is proportional to

$$e^{-E/kT} = e^{-G_0(v)/0.6952T} \tag{5.1}$$
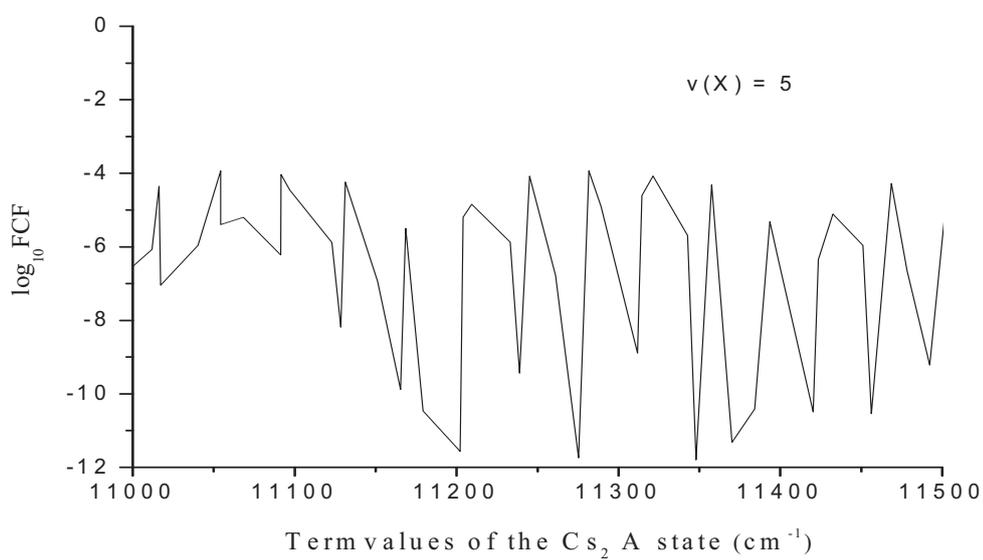

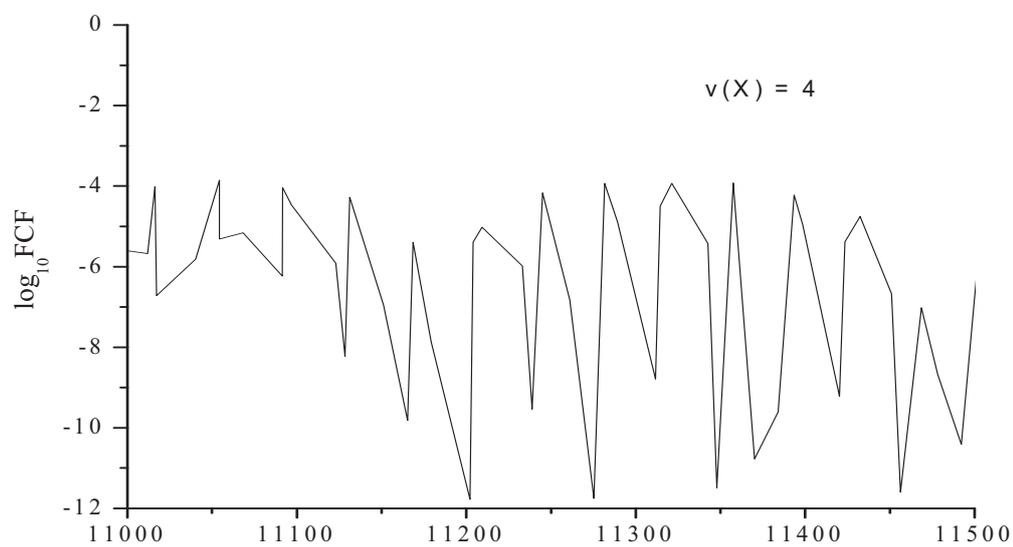

(a)
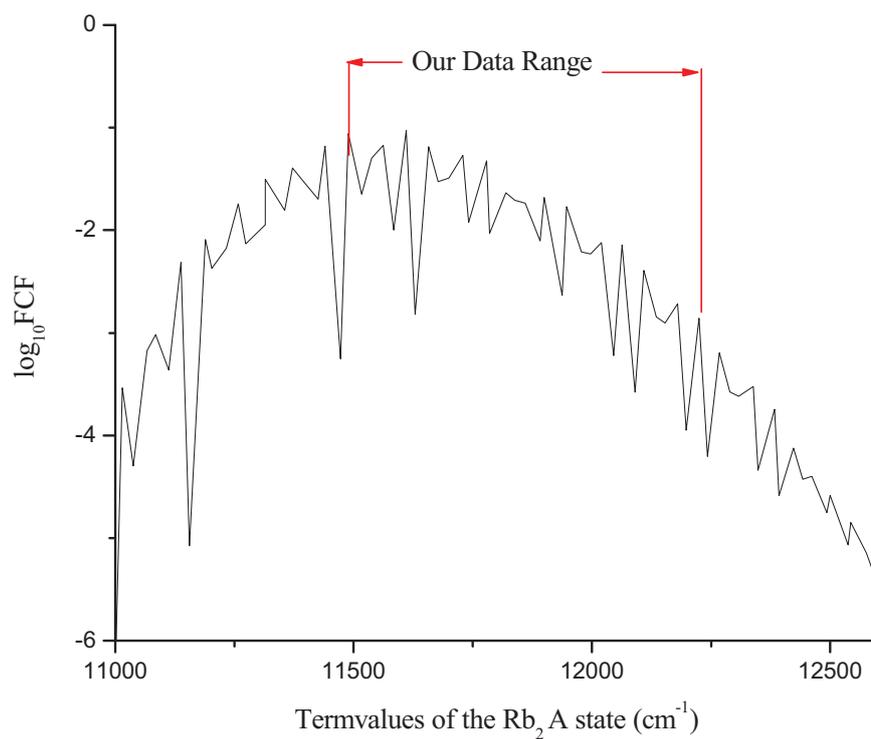

(b)

Figure 5.6 (a) Logarithm of the Franck- Condon factors for transitions between $v'' = 4$ and $v'' = 5$ ground states to A states of Cs_2. (b) Logarithm of the Franck- Condon factors for transitions between $v'' = 0$ ground state to A states of Rb_2.

where k is Boltzmann's constant and T is the sample temperature of 550K for our Cs_2 polarization experiment. Figure 5.6 shows the thermal population distribution of the vibrational levels of Cs_2 ground states. From this figure we see that the higher the vibrational level of the ground state, the lower population of the molecules.

5.3 Identifaction of the Rotational Quantum Numbers in the Polarization Spectra

5.3.1 Application of the Collision - Induced Lines to Mitigate the Difficulty in Identifying Isolated Pump Laser Transitions

As can be seen from Figure 5.3, we detected much weaker satellite lines due to collision-induced orientation transfer with ΔJ up to 12 in our Cs_2 polarization experiment. Due to the density of rovibrational lines in the electronic states of Cs_2 it was difficult to separate pump laser transitions from unrelated pump transitions. To mitigate this difficulty the wavelength of the probe laser was tuned to a satellite line and after that the pump laser was scanned around the original pump transition. A strong Doppler-free signal could be detected when the two lasers shared the same ground state. Then the pump laser was tuned to this newly labeled pump transition and the probe laser was scanned to get the strong P, R lines as well as new satellite lines.
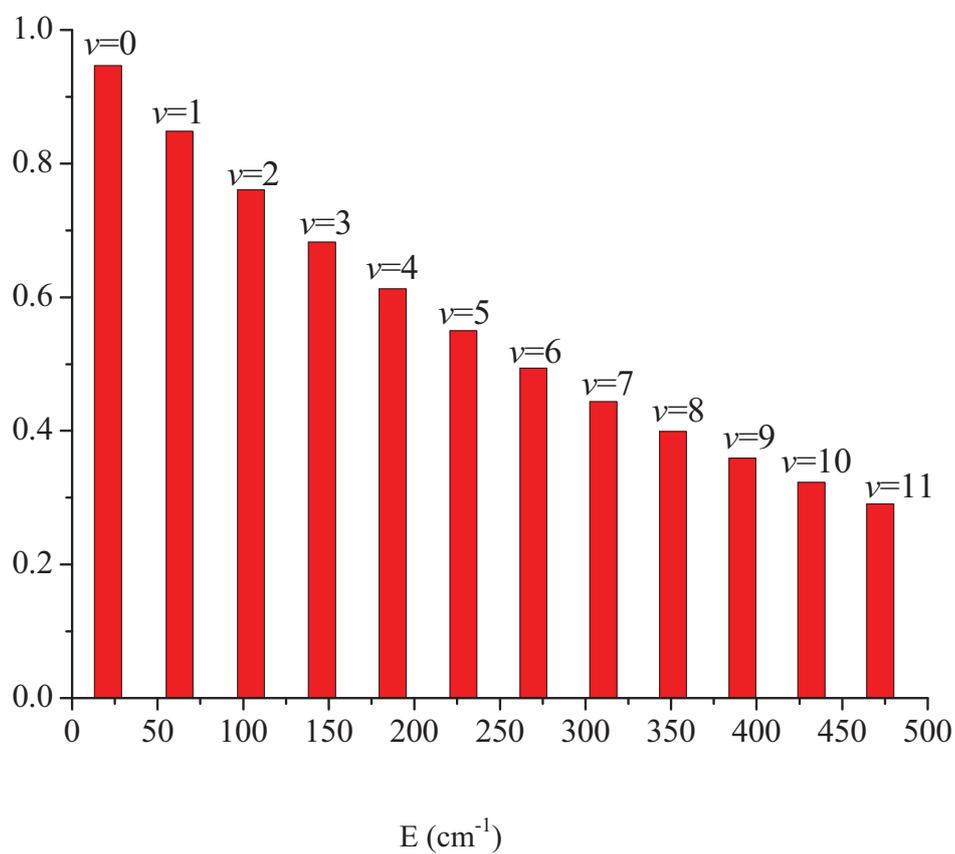

Figure 5.7 Thermal population distribution of the vibrational levels of Cs_2 $X^1\Sigma_g^+$ ground

state, given by $e^{-E/kT}$ for different v with T = 550K.

5.3.2 Advantages of This Technique

Compared to using a monochromator and resolved fluorescence spectroscopy to identify the pump laser transition quantum numbers, using the collisional satellite lines to isolate pump laser frequencies was much less time consuming. Since the rovibronic energy level structure of Cs_2 electronic states is very dense, it is difficult to resolve the $C^1\Pi_u \rightarrow X^1\Sigma_g^+$ fluorescence. Small scan steps and long integration time were necessary to obtain reliable fluorescence data scan using the SPEX 1404 double monochromator to confirm the pump transition rotational quantum number for the ground state, up to hours of time per scan. Ordinarily the fluorescence based assignment of the upper level rotational quantum number relies on accurate knowledge of the ground state rovibrational energy levels and their energy separations. The experimentally observed R, P pair separation is simply compared with the second combination differences $\Delta_2 F(J'') = F(J''+1) - F(J''-1)$ where F stands for the termvalue. Using this new technique, we could find a new pump transition in a few minutes.

This method is also more accurate than the monochromator scan, which has lower resolution. Another advantage of this method is that it greatly extended the range of the rotational quantum numbers that we could obtain from the experiment.

5.4 Conclusion

We obtained high resolution spectra of the $A^1\Sigma_u^+ / b^3\Pi_u \leftarrow X^1\Sigma_g^+$ transitions of the Rb_2 and Cs_2 molecules by the technique of Doppler-free optical–optical double resonance polarization spectroscopy. The accurate wavenumbers of the direct lines and the satellite

lines due to collisional orientation transfer were recorded. The spin-orbit perturbations

between the $A^1\Sigma_u^+$ and $b^3\Pi_u$ states complicated the spectra. The theoretical analysis of

the experimental data will be discussed in the next chapter.

CHAPTER 6

THEORETICAL ANALYSIS OF
THE $A^1\Sigma_u^+$ AND $b^3\Pi_u$ PERTURBED STATES

6.1 $A^1\Sigma_u^+$ / $b^3\Pi_u$ States of Rb$_2$ and Cs$_2$ mixed by the Spin-Orbit Interaction

The spin-orbit interaction couples the spin and orbital angular momenta of the electrons [1]. Spin-orbit splitting and coupling terms have been studied experimentally and theoretically for many years [2-4]. The atomic spin-orbit coupling strength (the fine structure splitting) of the first excited p state ($^2P_{3/2}$ -$^2P_{1/2}$) of the alkali atoms is 0.34cm^{-1} for Li (2p) , 17.2cm^{-1} for Na (3p), 57.7cm^{-1} for K(4p), 237.6cm^{-1} for Rb(5p), and 554.0cm^{-1} for Cs(6p). The first excited molecular electronic states in the $A^1\Sigma_u^+$ ~ $b^3\Pi_u$ complex of states of Rb$_2$ and Cs$_2$ are highly perturbed because of the strong spin – orbit interaction for heavier atoms and molecules.

There has been many global deperturbation studies of the spin-orbit interaction of the $A^1\Sigma_u^+$ / $b^3\Pi_u$ electronic states of the alkali diatomic molecules Li$_2$ [5-8], Na$_2$ [9-13], K$_2$ [14-18] and Rb$_2$ [19,20]. The goal of this research was to determine the singlet~triplet character of each rovibrational level and their energies to identify gateway levels for Perturbation-Faciliatated Optical Resonance (PFOODR) excitation to the higher lying

excited electronic states, which could not be reached from the singlet ground state $X^1\Sigma_g^+$ [21]. Traditionally band-by-band methods [13] were applied to analyze the $A^1\Sigma_u^+$ / $b^3\Pi_u$ electronic states of the lighter alkali molecules. The spin-orbit coupling matrix elements for many vibrational levels could be generated. However, for the heavier alkali dimers a more systematic global deperturbation process is necessary since the spin-orbit interaction is much stronger and perturbations are no longer local. The spin-orbit coupling matrix elements are even larger than the vibrational energy intervals in the heavier alkali dimers.

Such global deperturbation analyses, resulting in complete characterization of the rovibrational level structure, including the singlet~triplet character of the $A^1\Sigma_u^+ \sim b^3\Pi_u$ states and the internuclear distance dependent spin-orbit functions, have been reported for Na_2 [9,13], K_2 [15], Rb_2 [20] and Cs_2 [22-24]. The spin-orbit splitting for the NaK $A^1\Sigma_u^+$ / $b^3\Pi_u$ state has been studied by Ross *et al.* [25] and Sun *et al.* [26]. These experimental observations were later followed by *ab initio* calculations [27,28] of the potential energy functions and spin-orbit functions for the Cs_2 $A^1\Sigma_u^+$ / $b^3\Pi_u$ electronic states, performed at Moscow state University and Temple University. This Thesis deals with the acquisition and analysis of the data for the global deperturbation of the spin-orbit interaction for the Rb_2 and Cs_2 A~b complexes. We now describe the theoretical analysis used in the global deperturbation process.

6.2 Discrete Variable Representation (DVR) Method

6.2.1 Introduction to DVR Method

Laser spectroscopic techniques and traditional methods of analysis have been applied to analyze the spectra of the $A^1\Sigma_u^+$ and $b^3\Pi_u$ states of Li$_2$, Na$_2$, K$_2$ and NaK. Traditionally the transition frequencies obtained from the experiment are fitted to an analytical expression such as the Dunham expansion [29]. The local perturbations can be isolated in such an analysis, since they appear with larger residuals in the fit. The unperturbed levels can then be used in a new Dunham fit to produce new molecular constants, and from those by using the semi- classical Rydberg – Klein – Rees (RKR) [30] method, an RKR potential energy curve can be calculated.

The traditional methods cannot, however, be used to analyze the strong spin – orbit coupling between the two A~b complex of states of the heavier alkali – metal dimers. The discrete variable representation (DVR), a numerical method (also known as the Fourier Grid Hamiltonian (FGH) method), was applied to study the lowest excited states, the A$^1\Sigma$ state and the b$^3\Pi$ state, of the heavier alkali – metal dimers such as Na$_2$, Rb$_2$ and RbCs.

The DVR method has proved to be a useful tool for solving problems in quantum mechanics numerically [31,32]. J. C. Light and coworkers have compared the DVR method and other representations [33]. The DVR method has been applied to a number of systems. M. R. Manaa *et. Al* [15] extracted accurate Dunham coefficients and potential curves for the perturbed A/b states of K$_2$ by using the DVR method together with the *ab initio* diagonal and off-diagonal spin-orbit functions. The Fourier grid representation is

the simplest DVR. Based on the eigenfunctions of a particle in a box, it can be used to study nonadiabatic effects in the dynamics of alkali-metal dimers [34].

6.2.2 Theory of DVR method

In the DVR method the internuclear distance R of the diatomic molecule in interval (R_0, R_N) is restricted to the uniformly spaced N-1 grid points:

$$R_i = R_0 + (R_N - R_0)i / N, i = 1,\ldots, N-1 \tag{6.1}$$

The matrix element for the potential operators is [35]:

$$V_{ij} = V(R_i)\delta_{ij}, \tag{6.2}$$

The DVR kinetic energy is written as:

$$H_{ij}^k = -\frac{\hbar^2}{2m}\Delta x \sum_{n=1}^{N-1} \phi_n(x_i)\phi_n''(x_j) \tag{6.3}$$

where $\Delta x = (R_N - R_0)/N$ is the spacing of the grid and ϕ_n is the wavefunction, which has the form:

$$\phi_n(x) = \left(\frac{2}{R_N - R_0}\right)^{1/2} \sin\left[\frac{n\pi(x - R_0)}{R_N - R_0}\right], n = 1, \ldots, N-1 \tag{6.4}$$

Since $\phi_n(x_0 = R_0) = \phi_n(x_N = R_N) = 0$ for particle-in-a-box eigenfunctions, only N-1

functions and N-1 points are considered. The matrix elements for the kinetic energy

operator $H^k = -\dfrac{\hbar^2}{2\mu}\dfrac{d^2}{dR^2}$ can be written as:

$$H_{ij}^k = -\frac{\hbar^2}{4\mu}\frac{\pi^2(-1)^{i-j}}{(R_0 - R_N)^2}\left\{\frac{1}{\sin^2[\pi(i-j)/2N]} - \frac{1}{\sin^2[\pi(i+j)/2N]}\right\} \tag{6.5}$$

when $i \neq j$ and

$$H_{ij}^k = -\frac{\hbar^2}{4\mu}\frac{\pi^2}{(R_0 - R_N)^2}\left\{\frac{2N^2+1}{3} - \frac{1}{\sin^2(\pi i/N)}\right\} \tag{6.6}$$

when $i = j$. The eigenfunction and eigenvalue of each electronic state can be obtained by

diagonalizing the total DVR Hamiltonian matrix. Spin – orbit coupling is important to the

study of the $A^1\Sigma_\mu$ and $b^3\Pi_\mu$ perturbed states of alkali dimers because it leads to the

singlet – triplet mixing and thus the fine structure splitting.

6.3 Analysis of the Experimental Data

6.3.1 Molecular Hamiltonian

The molecular Hamiltonian which includes the Born – Oppenheim potentials H_{BO}, radial kinetic energy H_K, nuclear rotation H_{rot}, and spin – orbit interaction H_{SO}, can be expressed as [1]:

$$H = H_{BO} + H_K + H_{SO} + H_{rot} \tag{6.7}$$

Here $H_K = -\left(\dfrac{\hbar^2}{2u}\right)\dfrac{d^2}{dR^2}$ is the kinetic energy operator, where u is the reduced mass of the system and R is the distance between the two nuclei.

In Cs_2 second – order spin – orbit (SO2) effects are significant because Cs_2 is a relatively heavy diatomic molecule. From [1], we see that the matrix elements of $H_{BO} + H_{SO} + H_{rot} + H_{SO2}$ are:

$$\left\langle {}^1\Sigma_u^+ \middle| H \middle| {}^1\Sigma_u^+ \right\rangle = U_A + (x+2)B + U_A^{so2}$$

$$\left\langle {}^3\Pi_{0u}^+ \middle| H \middle| {}^3\Pi_{0u}^+ \right\rangle = U_{b0}^+ + (x+2)B + U_{b0e}^{so2}$$

$$\left\langle {}^3\Pi_{0u}^- \middle| H \middle| {}^3\Pi_{0u}^- \right\rangle = U_{b0}^- + (x+2)B + U_{b0f}^{so2}$$

$$\left\langle {}^3\Pi_{1u} \middle| H \middle| {}^3\Pi_{1u} \right\rangle = U_{b0}^+ + (x+2)B + \xi_{b10}^{so}$$

$$\left\langle {}^3\Pi_{2u} \middle| H \middle| {}^3\Pi_{2u} \right\rangle = U_{b0}^+ + (x-2)B + \xi_{b10}^{so} + \xi_{b21}^{so}$$

$$\left\langle {}^1\Sigma_u^+ \middle| H \middle| {}^3\Pi_{0u}^+ \right\rangle = -\sqrt{2}\xi_{Ab0}^{so}$$

$$\left\langle {}^3\Pi_{0u} \middle| H \middle| {}^3\Pi_{1u} \right\rangle = -\sqrt{2x}B$$

$$\left\langle {}^{3}\Pi_{1u} \middle| H \middle| {}^{3}\Pi_{2u} \right\rangle = -\sqrt{2(x-2)}B$$

$$\left\langle {}^{1}\Sigma_{u}^{+} \middle| H \middle| {}^{3}\Pi_{1u} \right\rangle = -\sqrt{2x}B\eta \qquad (6.8)$$

where u is the reduced mass, $x = J\,(J+1)$, $B \equiv \dfrac{\hbar^2}{2uR^2}$ and $H^T = H$. Here H^T is the transpose of H. The potentials U_A and $U_{b0}^{\pm}$, $B \equiv \dfrac{\hbar^2}{2uR^2}$, as well the off diagonal spin-orbit function ξ_{Ab0}^{SO} and diagonal spin-obit function ξ_{b10}^{SO}, are functions of the internuclear distance R. ξ_{b10}^{SO} is the $\Omega = 1 - 0^{+}$ interval of the b state and ξ_{b21}^{SO} is the $\Omega = 2 - 1$ interval. Both of the two functions include the SO2 effect implicitly. As discussed in [36], the parameter η arises from second-order spin-orbit and electronic-rotational effects.

The SO2 functions can be expressed as [24]:

$$U_{A}^{SO2}(R) = \frac{2\left| \xi_{A-j}^{SO} \right|^{2}}{U_{A} - U_{j}} ; j \in (2)^{3}\Pi_{u},$$

$$U_{b0e}^{SO2}(R) = \frac{2\left| \xi_{b0-j}^{SO} \right|^{2}}{U_{b0}^{+} - U_{j}} ; j \in (2)^{1}\Sigma_{u}^{+},$$

$$U_{b0f}^{SO2}(R) = \sum_{j} \frac{2\left| \xi_{b0-j}^{SO} \right|^{2}}{U_{b0}^{-} - U_{j}} ; j \in (1-3)^{1}\Sigma_{u}^{+},$$

$$U_{b1e}^{SO2}(R) = \sum_{j} \frac{\left| \xi_{b1-j}^{SO} \right|^{2}}{U_{b1}^{+} - U_{j}} ; j \in (1-3)^{3}\Sigma_{u}^{+}, (1-2)^{1}\Pi_{u}. \qquad (6.9)$$

U_{b0f}^{SO2} is large and positive for small R and becomes negative for large R. That the $a^{3}\Sigma_{u}^{+}$ potential lies below the $b^{3}\Pi_{0u}^{-}$ potential shifts the $b^{3}\Pi_{0u}^{-}$ energy upward. The SO2 shift

is negative for large R because the $b^3\Pi_{0u}^-$ potential approaches various ungerade potentials from below in this region.

The difference between the eigenvalues calculated from the fitted potentials with and without the off-diagonal ξ_{Abo}^{SO} coupling function is the theoretical value of the SO contribution. It comes from the strong spin-orbit coupling between the triplet $b^3\Pi_{0u}$ state and the nearby singlet $A^1\Sigma_u^+$ state.

The step size $\Delta R_{min} = (a-b)/N$ should be smaller than the local de Broglie wavelength, which is small near the deepest part of the potential curve and becomes much larger for larger internuclear separations. The dimension of the matrix is unmanageable if we use the same ΔR_{min} in the numerical calculations for small and large R. Transformation is performed to reduce the matrix dimensions. [35].

The nonlinear coordinate transformation which leads to the smallest matrix dimension has the form:

$$y = u(R) = \int_R^\infty \frac{dx}{R_0} \sqrt{\left(\frac{R_0}{x+R_s}\right)^n} = -\frac{1}{(n/2)-1}\left(\frac{R_0}{R+R_s}\right)^{n/2-1} \tag{6.10}$$

where n characterizes the long range tail of the potentials. R_0 and R_s are free parameters. The transformation ensures that, as the local de Broglie wavelength increases at large

internuclear separations, the step size also increases. The kinetic energy operator is transformed into the form:

$$H^K = -\frac{\hbar^2}{2u}\frac{d^2}{dR^2} = -\frac{\hbar^2}{2u}\left\{p(y)\frac{d^2}{dy^2} + q(y)\frac{d}{dy}\right\} \tag{6.11}$$

with

$$p(y) = \frac{1}{[U'(y)]^2} \quad \text{and} \quad q(y) = -\frac{U''(y)}{[U'(y)]^3} \tag{6.12}$$

where U(y) is the inverse transformation of $y = u(R)$. The transformed wavefunction $\Phi(y)$ is defined by:

$$\Psi(R) = \frac{\Phi(y)}{\sqrt{U'(y)}} \tag{6.13}$$

The new Schrodinger equation has the form:

$$\left[\frac{\hbar^2}{2u}\left\{-\frac{1}{U'(y)}\frac{d^2}{dy^2}\frac{1}{U'(y)} - \frac{1}{2}\frac{U^{(3)}(y)}{[U'(y)]^3} + \frac{3}{4}\frac{[U''(y)]^2}{[U'(y)]^4}\right\} + V(U(y))\right]\Phi(y) = E\Phi(y) \tag{6.14}$$

From this equation we see that the first term on the left hand side of the equation serves as kinetic energy operator and the remaining terms on the left hand side corresponded to

114

spin-independent potentials. The eigenvalues and eigenfunctions can be obtained by the diagonalization of the DVR matrix for each J.

6.3.2 Analytic Potential Functions

An Expanded Morse Oscillator (EMO) function [37-39] can be used to analytically represent the empirical potential energy curves (PECs) of the perturbed $A^1\Sigma_u^+ \sim b^3\Pi_u$ electronic states converging to the appropriate dissociation limit:

$$U(R) = T_e + D_e\left[1 - e^{-a(R-R_e)}\right]^2$$

$$\alpha(R) = \sum_{i=0}^{N} a_i \left(\frac{R^p - R_{ref}^P}{R^p + R_{ref}^P}\right)^i \qquad (6.15)$$

where R is in Å, $P=3$, $R_{ref} =5.0$ Å, T_e and D_e are in cm^{-1}, and the other parameters are dimensionless.

The matrix elements of the spin-orbit operator are given by:

$$H_{SO} = \frac{\alpha^2}{2}\sum_N\sum_i \frac{Z_N}{R_{iN}^3}l_i \cdot s_i - \frac{\alpha^2}{2}\sum_{i\neq j}\frac{1}{r_{ij}^3}\left[R_{ij} \times p_i\right]\cdot\left(s_i + 2s_j\right), \qquad (6.16)$$

where α is the fine structure constant , s_i is the spin of electron i, R_{iN} is the separation between the ith electron and charge Z_N, l_i is the electron orbital angular momentum relative to the nucleus, R_{ij} is the separation between electron i and j, and p_i is the

momentum of electron i. The first term of this equation is a one electron operator that describes spin-orbit interactions between one nucleus and one electron. The second term is a two-electron operator that describes the spin-orbit interactions between electrons.

6.4 Fit of the Experimental Data

6.4.1 Fitting Procedures

The dimension of the DVR Hamiltonian for a single electronic state equals the square of the number of R mesh points N. For coupled states with p different electronic states, the dimension becomes $pN \times pN$. Two channel calculations include only the $^1\Sigma_u^+$ and $^3\Pi_{0u}^+$ electronic states. $^3\Pi_{1u}$ levels are added for the three channel calculations. No spectral lines from the $^3\Pi_{2u}$ levels were observed in the experiments, but the $^3\Pi_{2u}$ components are coupled with the $^3\Pi_{1u}$ levels and thus indirectly affect the $^3\Pi_{0u}^+$ levels. The components of the $^3\Pi_{2u}$ are also included in the four channel calculations.

6.4.2 Fitting Results

Our Rb$_2$ experimental data, together with data from Laboratoire Aime Cotton and Lyon University, were used in the global analysis of data on $A^1\Sigma_u^+$ and $b^3\Pi_u$ states of Rb$_2$ [20]. Parameters of the $A^1\Sigma_u^+$ and $b^3\Pi_u$ states of Rb$_2$ were generated by applying the DVR method.

Our Cs_2 experimental data, together with the laser-induced fluorescence Fourier transform spectroscopy (LIF FTS) data from Laboratoire Aime Cotton and University of Latvia, Cs_2 cold molecules data from Innsbruck University, and experimental data from Tsinghua University were used in the global analysis of data on $A^1\Sigma_u^+$ and $b^3\Pi_u$ states of Cs_2 by applying the DVR program created by Dr. T. Bergeman from SUNY, Stony Brook. All the data used in this global fit are shown in Figure 6.1. Potential curves and the parameters for the $A^1\Sigma_u^+$ and $b^3\Pi_u$ states were derived from the experimental data. Details of the fit can be found in reference [24].

The term values calculated from the DVR program and the term values obtained from our Cs_2 polarization spectroscopy experimental data are shown in Figure 6.2. For illustration purposes the rotational energy $B_v(J(J+1))= 0.0091*J(J+1)$ has been subtracted from the term values. Here J is the rotational quantum number, and B_v is the rotational constant. Theoretically, the lines with the least slope are from the $A^1\Sigma_u^+$ states because the rotational constant of the A state is smaller. The lines with the steeper slope are from the $b^3\Pi_{1u}$ states. The lines with a slope that is between the $A^1\Sigma_u^+$ states and the $b^3\Pi_{1u}$ are the $b^3\Pi_{0u}$ states. From Figure 6.2 it is evident that most of the data we obtained from the Cs_2 polarization spectroscopy experiment belong to the $A^1\Sigma_u^+$ state. The singlet states and the triplet states are highly mixed, and that is why it is impossible to assign vibrational levels to the data.
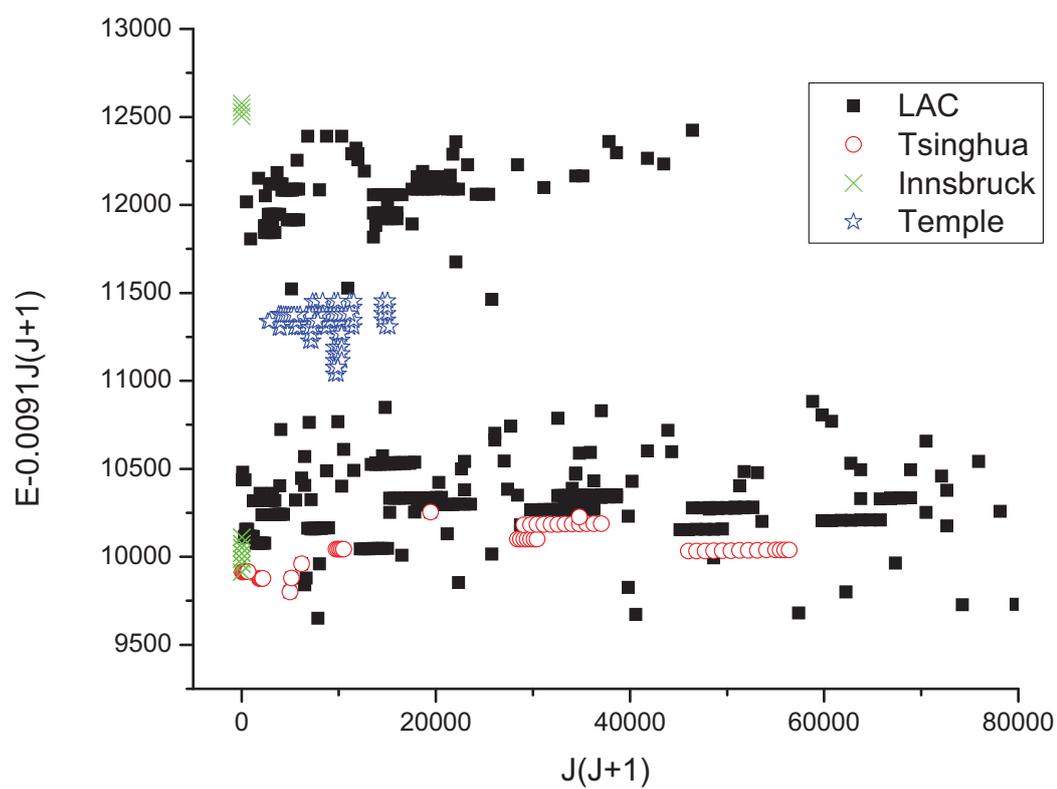

Figure 6.1 Experimental data used in the global analysis of the $A^1\Sigma_u^+$ and $b^3\Pi_u$ perturbed states of Cs_2.

The identified transitions and their rotational and vibrational quantum numbers from our

Rb$_2$ and Cs$_2$ polarization spectroscopy experiments are listed in the Appendix.
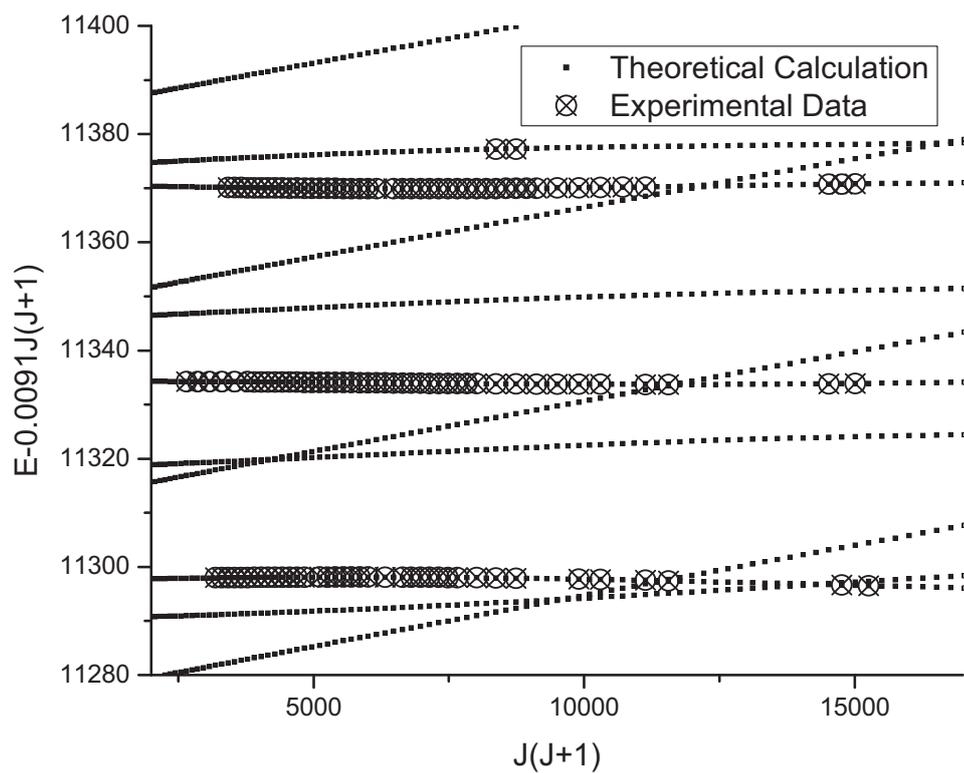

Figure 6. 2 Some of the term values obtained from the Cs$_2$ polarization spectroscopy experiment. Smaller filled circles are theoretically calculated term values. The circles with crosses in the middle are experimental data.

APPENDIX

Identified fluorescence spectral lines for the Rb$_2$ polarization experiment. The unit for the fluorescence lines is cm^{-1}. The n' values give the energy eigenvalue number calculated for the upper $A^1\Sigma_u^+ \sim b^3\Pi_u$ state.
